Applicative Bidirectional Programming

Mixing Lenses and Semantic Bidirectionalization

KAZUTAKA MATSUDA
Graduate School of Information Sciences, Tohoku University
and
MENG WANG
Department of Computer Science, University of Bristol

Abstract

A bidirectional transformation is a pair of mappings between source and view data objects, one in each direction. When the view is modified, the source is updated accordingly with respect to some laws. One way to reduce the development and maintenance effort of bidirectional transformations is to have specialized languages in which the resulting programs are bidirectional by construction—giving rise to the paradigm of bidirectional programming.

In this paper, we develop a framework for applicative-style and higher-order bidirectional programming, in which we can write bidirectional transformations as unidirectional programs in standard functional languages, opening up access to the bundle of language features previously only available to conventional unidirectional languages. Our framework essentially bridges two very different approaches of bidirectional programming, namely the lens framework and Voigtländer’s semantic bidirectionalization, creating a new programming style that is able to obtain benefits from both.

1 Introduction

Bidirectionality is a reoccurring aspect of computing: transforming data from one format to another, and requiring a transformation in the opposite direction that is in some sense an inverse. The most well-known instance is the view-update problem (Bancilhon & Spyratos 1981; Dayal & Bernstein 1982; Fegaras 2010; Hegner 1990) from database design: a “view” represents a database computed from a source by a query, and the problem comes when translating an update of the view back to a “corresponding” update on the source.

But the problem is much more widely applicable than just to databases. It is central in the same way to most interactive programs, such as desktop and web applications: underlying data, perhaps represented in XML, is presented to the user in a more accessible format, edited in that format, and the edits translated back in terms of the underlying data (Hayashi et al. 2007; Hu et al. 2004; Rajkumar et al. 2013). Similarly for model transformations, playing a substantial role in software evolution: having transformed a high-level model into a lower-level implementation, for a variety of reasons one often needs to reverse engineer a revised high-level model from an updated implementation (Xiong et al. 2007; Yu et al. 2012).
Kazutaka Matsuda and Meng Wang

Using terminologies originated from the lens framework (Bohannon et al. 2008; Foster et al. 2007, 2008), bidirectional transformations, coined lenses, can be represented as pairs of functions known as get of type $S \rightarrow V$ and put of type $S \rightarrow V \rightarrow S$. Function get extracts a view from a source, and put takes both an updated view and the original source as inputs to produce an updated source. An example definition of a bidirectional transformation in Haskell notation is

```haskell
data Lens s v = Lens { get :: s \rightarrow v, put :: s \rightarrow v \rightarrow s }

fstL :: Lens (a, b) a
fstL = Lens (\(\lambda (a, _) \rightarrow a\)) (\(\lambda (_, b) a \rightarrow (a, b)\))
```

A value $\ell$ of type $Lens s v$ is a lens that has two function fields namely get and put, and the record syntax overloads the field names as access functions: $get \ell$ has type $s \rightarrow v$ and $put \ell$ has type $s \rightarrow v \rightarrow s$. The datatype is used in the definition of $fstL$, where the first element of a source pair is projected as the view, and may be updated to a new value.

Not all bidirectional transformations are considered “reasonable” ones. The following laws are generally required to establish bidirectionality:

- $put \ell s (get \ell s) = s$ \hspace{1cm} (Acceptability)
- $get \ell s' = v$ if $put \ell s v = s'$ \hspace{1cm} (Consistency)

for all $s$, $s'$ and $v$. Note that in this paper, we write $e = e'$ with the assumption that neither $e$ nor $e'$ is undefined. Here Consistency (also known as the PutGet law (Foster et al. 2007)) roughly corresponds to right-invertibility, ensuring that all updates on a view are captured by the updated source; and Acceptability (also known as the GetPut law (Foster et al. 2007)), prohibits changes to the source if no update has been made on the view. Collectively, the two laws define well-behavedness (Bancilhon & Spyratos 1981; Foster et al. 2007; Hegner 1990). A bidirectional transformation $Lens get put$ is called well-behaved if it satisfies well-behavedness. The above example $fstL$ is a well-behaved bidirectional transformation.

By dint of hard effort, one can construct separately the forward transformation get and the corresponding backward transformation put. However, this is a significant duplication of work, because the two transformations are closely related. Moreover, it is prone to error, because they do really have to correspond with each other to be well-behaved. And, even worse, it introduces a maintenance issue, because changes to one transformation entail matching changes to the other. Therefore, a lot of work has gone into ways to reduce this duplication and the problems it causes; in particular, there has been a recent rise in linguistic approaches to streamlining bidirectional transformations (Barbosa et al. 2010; Bohannon et al. 2008; Foster et al. 2007, 2008, 2010; Hidaka et al. 2010; Hu et al. 2004; Matsuda & Wang 2013, 2014; Matsuda et al. 2007; Mu et al. 2004; Pacheco et al. 2014b; Rajkumar et al. 2013; Voigtlander 2009a; Voigtlander et al. 2010, 2013; Wang & Najd 2014; Wang et al. 2010, 2011, 2013).

Ideally, bidirectional programming should be as easy as usual unidirectional programming. For this to be possible, techniques of conventional languages such as applicative-style and higher-order programming need to be available in the bidirectional languages, so that existing programming idioms and abstraction methods can be ported over. At the minimum, programmers shall be allowed to treat functions as first-class objects and have them applied
explicitly. Moreover, it is beneficial to be able to write bidirectional programs in the same style of their gets, because as cultivated by traditional unidirectional programming, programmers normally start with (at least mentally) constructing a get before trying to make it bidirectional.

However, existing bidirectional programming frameworks fall short of this goal by quite a distance. The lens bidirectional programming framework (Barbosa et al. 2010; Bohannon et al. 2008; Foster et al. 2007, 2008, 2010; Hu et al. 2004; Mu et al. 2004; Pacheco et al. 2014b; Rajkumar et al. 2013; Wang et al. 2010, 2013), the most influential of all, composes small lenses into larger ones by special lens combinators. The combinators preserve well-behavedness, and thus produce bidirectional programs that are correct by construction. Lenses are impressive in many ways: they are highly expressive and adaptable, and in many implementations a carefully crafted type system guarantees the totality of the bidirectional transformation. But at the same time, like many other combinator-based languages, lenses restrict programming to the point-free style, which may not be the most appropriate in all cases. We have learned from past experiences (McBride & Paterson 2008; Paterson 2001) that a more convenient programming style does profoundly impact on the popularity of a language.

Research on bidirectionalization (Hidaka et al. 2010; Matsuda & Wang 2013, 2014; Matsuda et al. 2007; Voigtlander 2009a; Voigtlander et al. 2010, 2013; Wang & Najd 2014; Wang et al. 2010, 2013), which mechanically derives a suitable put from an existing get, shares the same spirit with us to some extent. The gets can be programmed in a unidirectional language and passed in as objects to the bidirectionalization engine, which performs program analysis and then generation of puts. However, the existing bidirectionalization methods are whole program analyses; there is no better way to compose individually constructed bidirectional transformations.

In this paper, we develop a novel bidirectional programming framework:

- As lenses, it supports composition of user-constructed bidirectional transformations, and well-behavedness of the resulting bidirectional transformations is guaranteed by construction.
- As a bidirectionalization system, it allows users to write bidirectional transformations almost in the same way as that of gets, in an applicative and higher-order programming style.

The key idea of our proposal is to lift lenses of type $\text{Lens } (A_1, \ldots, A_n) \to B$ to lens functions of type

$$\forall s. L s A_1 \to \cdots \to L s A_n \to \cdots \to L s B$$

where $L$ is a type-constrained version of $\text{Lens}$ (Sections 2 and 3). The $n$-ary tuple $(A_1, \ldots, A_n)$ above is then generalized to data structures such as lists in Section 4. This function representation of lenses is open to manipulation in an applicative style, and can be passed to higher-order functions directly. For example, we can write a bidirectional version of $\text{unlines}$, defined by

\[
\text{unlines} :: [\text{String}] \to \text{String} \\
\text{unlines} [\ ] = "" \\
\text{unlines} (x:xs) = x ++ "\n" ++ \text{unlines} xs
\]
Kazutaka Matsuda and Meng Wang

as below.

\[
\text{unlines}_F :: [Ls \text{ String}] \rightarrow Ls \text{ String} \\
\text{unlines}_F [] = \text{new } "\n" \\
\text{unlines}_F (x : xs) = \text{lift2 catLineL} (x, \text{unlines}_F xs)
\]

where \(\text{catLineL}\) is a lens version of \(\lambda x y \rightarrow x \, \text{++} \, \text{\"\n\"} \, \text{++} \, y\). In the above, except for the noise of \text{new} and \text{lift2}, the definition is faithful to the original structure of \text{unlines}' definition, in an applicative style. With the heavy-lifting done in defining the lens function \(\text{unlines}_F\), a corresponding lens \(\text{unlines}_L :: \text{Lens} [\text{String}] \text{ String}\) is readily available through straightforward unlifting: \(\text{unlines}_L = \text{unliftT} \text{unlines}_F\). In the forward direction, lens \(\text{unlines}_L\) is the same as the unidirectional function \(\text{unlines}\):

Main> \text{get unlines}_L ["a", "b", "c"]
"a\n\nb\nc\n"

In the backward direction, changes to the list elements in the view are put back to the source:

Main> \text{put unlines}_L ["a", "b", "c"] ["AA\nBB\nCC\n"]
["AA", "BB", "CC"]

With this definition, structural updates (i.e., changes to the length of the view list) are not allowed. For example, \(\text{put unlines}_L ["a", "b", "c"] \text{ "AA\nBB\nCC\n"}\) and \(\text{put unlines}_L ["a", "b", "c"] \text{ "$AA\nBB\nCC\n\nDD\n" result in exceptions. In Section 6, we explain that this restriction on updates is statically reflected in the type of \text{unlines}_F, and may be relaxed at the cost of the simplicity of the definition.

In Section 5, we demonstrate the expressiveness of our core system through a realistic example (bidirectional evaluator for a higher-order programming language), and then extend the core system in two different dimensions, showing a smooth integration of our framework with both lenses and bidirectionalization approaches in Section 6. We deploy the extended system in the context of XML transformations (Section 7), before proving the correctness theorem (Section 8). We discuss related techniques in Section 9, in particular making connection to semantic bidirectionalization (Matsuda & Wang 2013, 2014; Voigtländer 2009a; Wang & Najd 2014), followed by conclusion in Section 10. An implementation of our idea is available from https://hackage.haskell.org/package/app-lens.

Notes on Proofs and Examples. To simplify the formal discussion, we assume that all functions except \text{puts} are total and no data structure contains \(\bot\). To deal with the partiality of \text{puts}, we assume that a \text{put} function of type \(A \rightarrow B \rightarrow A\) can be represented as a total function of type \(A \rightarrow B \rightarrow \text{Maybe A}\), which upon termination will produce either a value \text{Just a} or an error \text{Nothing}.

We strive to balance the practicality and clarity of examples. Very often we deliberately choose small but hopefully still illuminating examples aiming at directly demonstrating the and only the theoretical issue being addressed. In addition, we include in Section 5 a sizeable application and would like to refer interested readers to https://bitbucket.org/kztk/app-lens for examples ranging from some general list functions in Prelude to the specific problem of XML transformations.
Applicative Bidirectional Programming

A preliminary version of this paper appeared in ICFP’15 (Matsuda & Wang 2015), under the title “Applicative Bidirectional Programming with Lenses”. The major differences to the preliminary version include proofs in Section 8 and Appendix A, more detailed discussion to Voigtländer’s original bidirectionalization in Section 6.2, and an XML transformation example in Section 7 involving the extensions discussed in Section 6, together with the improvement of overall presentation and correction of technical errors in Section 3.

2 Bidirectional Transformations as Functions

Conventionally, bidirectional transformations are represented directly as pairs of functions (Foster et al. 2007; Hegner 1990; Hidaka et al. 2010; Hu et al. 2004; Matsuda & Wang 2013, 2014; Matsuda et al. 2007; Mu et al. 2004; Voigtländer 2009a; Voigtländer et al. 2010, 2013; Wang & Najd 2014; Wang et al. 2010, 2011, 2013) (see the datatype Lens defined in Section 1). In this paper, we use lenses to refer specifically to bidirectional transformations in this representation.

Lenses can be constructed and reasoned about compositionally. For example, with the composition operator “\(\circ\)"

\[
(\circ) : \text{Lens } b \rightarrow \text{Lens } a \rightarrow \text{Lens } c
\]

\[
(\text{Lens } \text{get}_2 \circ \text{put}_2) \circ (\text{Lens } \text{get}_1 \circ \text{put}_1) = \\
\text{Lens } (\text{get}_2 \circ \text{get}_1) (\lambda s v \rightarrow \text{put}_1 s (\text{put}_2 (\text{get}_1 s) v))
\]

we can compose \(\text{fst}_L\) to itself to obtain a lens that operates on nested pairs, as below.

\[
\text{fstTri}_L : \text{Lens } ((a, b), c) a
\]

\[
\text{fstTri}_L = \text{fst}_L \circ \text{fst}_L
\]

Well-behavedness is preserved by such compositions: \(\text{fstTri}_L\) is well-behaved by construction assuming well-behaved \(\text{fst}_L\).

The composition operator “\(\circ\)” is associative, and has the identity lens \(\text{id}_L\) as its unit.

\[
\text{id}_L : \text{Lens } a a
\]

\[
\text{id}_L = \text{Lens } \text{id} (\lambda x \rightarrow x)
\]

This means that the set of (both well-behaved and not-necessarily-well-behaved) lenses forms a category, where objects are types (sets in our setting), and morphisms from \(A\) to \(B\) are lenses of type \(\text{Lens } A \rightarrow \text{Lens } B\).

2.1 Basic Idea: A Functional Representation Inspired by Yoneda

Our goal is to develop a representation of bidirectional transformations such that we can apply them, pass them to higher-order functions and reason about well-behavedness compositionally.

Inspired by the Yoneda embedding in category theory (Mac Lane 1998), we lift lenses of type \(\text{Lens } a b\) to polymorphic functions of type

\[
\forall a. \text{Lens } s a \rightarrow \text{Lens } s b
\]

by lens composition
Kazutaka Matsuda and Meng Wang

\[ \text{lift} :: \text{Lens } a \, b \to (\forall s. \text{Lens } s \, a \to \text{Lens } s \, b) \]

\[ \text{lift } \ell = \lambda x \to \ell \hat{\delta} x \]

Intuitively, a lens of type \( \text{Lens } s \, A \) with the universally quantified type variable \( s \) in a lifted function can be seen as an updatable datum of type \( A \), and a lens of type \( \text{Lens } A \, B \) as a transformation of type \( \forall s. \text{Lens } s \, A \to \text{Lens } s \, B \) on updatable data. We call such lifted lenses \textit{lens functions}.

The lifting function \( \text{lift} \) is injective, and has the following left inverse.

\[ \text{unlift} :: (\forall s. \text{Lens } s \, a \to \text{Lens } s \, b) \to \text{Lens } a \, b \]

\[ \text{unlift } f = f \, \text{id}_L \]

Since lens functions are normal functions, they can be composed and passed to higher-order functions in the usual way. For example, \( \text{fstTri}_L \) can now be defined with the usual function composition.

\[ \text{fstTri}_L :: \text{Lens} ((a, b), c) \, a \]

\[ \text{fstTri}_L = \text{unlift} \, (\text{lift } \text{fst}_L \circ \text{lift } \text{fst}_L) \]

Alternatively in a more applicative style, we can use a higher-order function \( \text{twice} :: (a \to a) \to a \to a \) as below.

\[ \text{fstTri}_L = \text{unlift} \, (\lambda x \to \text{twice} \, (\text{lift } \text{fst}_L) \, x) \]

where \( \text{twice } f \, x = f \, (f \, x) \)

Like many category-theory inspired isomorphisms, this functional representation of bidirectional transformations is not unknown (Ellis 2012); but its formal properties and applications in practical programming have not been investigated before.

### 2.2 Formal Properties of Lens Functions

We reconfirm that \( \text{lift} \) is injective with \( \text{unlift} \) as its left inverse.

**Proposition 1.** \( \text{unlift} \, (\text{lift } \ell) = \ell \) for all lenses \( \ell :: \text{Lens } A \, B \).

We say that a function \( f \) \textit{preserves well-behavedness}, if \( f \, \ell \) is well-behaved for any well-behaved lens \( \ell \). Functions \text{lift} and \text{unlift} have the following desirable properties.

**Proposition 2.** \( \text{lift } \ell \) preserves well-behavedness if \( \ell \) is well-behaved.

**Proof**
Immediate from the fact that \( \hat{\delta} \) preserves well-behavedness (Foster et al. 2007).

**Proposition 3.** \( \text{unlift } f \) is well-behaved if \( f \) preserves well-behavedness.

As it stands, the type \( \text{Lens} \) is open and it is possible to define lens functions through pattern-matching on the constructor. This becomes a problem when we want to guarantee that \( f :: \forall s. \text{Lens } s \, A \to \text{Lens } s \, B \) preserves well-behavedness. For example, the following \( f \) does not preserve well-behavedness.

\[ f :: \text{Lens } s \, \text{Int} \to \text{Lens } s \, \text{Int} \]

\[ f \, (\text{Lens } g \, p) = \text{Lens } g \, (\lambda s \_ \to p \, s \_ \_ ) \]
Applicative Bidirectional Programming

Here the input lens is pattern matched and the `get/put` components are used directly in constructing the output lens, which breaks encapsulation and blocks compositional reasoning of behaviors. Moreover, it is worth mentioning that `lift` is not surjective due to the exposure of `Lens`. The following $f'$ is an example that `lift` cannot produce, i.e., `lift (unlift $f'$) $\neq f'$.

\[ f' :: Eq a \Rightarrow Lens s (Maybe a) \to Lens s (Maybe a) \]
\[ f'(Lens g p) = Lens g (\lambda s v \to if v == g s then s else p (p s Nothing) v) \]

For example, for a well-behaved lens

\[ \ell :: Lens (Maybe (Int, Int)) (Maybe Int) \]
\[ \ell = Lens g p \]
\[ \text{where } g \text{ Nothing} = Nothing \]
\[ g \text{ Just s} = \text{Just} (\text{fst } s) \]
\[ p \text{ Nothing Nothing} = Nothing \]
\[ p \text{ Just s} (\text{Just } v) = \text{Just } (v, \text{snd } s) \]

we have `put ($f'$ $\ell$) (Just (1, 2)) (Just 3) = ⊥ while `put` (`lift` (`unlift` $f'$) $\ell$) (Just (1, 2)) (Just 3) = `Just` (3, 2).

In our framework the intention is that all lens functions are constructed through lifting, which sees bidirectional transformations as atomic objects. Thus, we require that `Lens` is used as an “abstract type” in defining lens functions of type $\forall s. \text{Lens } s A \to \text{Lens } s B$. That is, we require that lens values must be produced and consumed only by using lifted lens functions. This requirement is formally written as follows.

**Definition 1 (Abstract Nature of Lens).** We say `Lens` is abstract in $f :: \tau$ if there is a polymorphic function $h$ of type

\[ \forall \ell. (\forall a b. \ell a b \to (\forall s. \ell s a \to \ell s b)) \to (\forall a b. (\forall s. \ell s a \to \ell s b) \to \text{Lens } a b) \to \tau' \]

where $\tau' = \tau [\ell \to \text{Lens}]$ and $f = h \ell$ unlift.

Essentially, the polymorphic $\ell$ in $h$’s type prevents us from using the constructor `Lens` directly, while the first functional argument of $h$ (which is `lift`) provides the (only) means to produce and consume `Lens` values. For example, for a function lift $f_{\ell} :: \text{Lens } s (a,b) \to \text{Lens } s a$, we have a function $h \text{ lift}_{\ell}$ = $\ell' f_{\ell} :: \forall \ell. (\forall a b. \text{Lens } a b \to (\forall s. \ell s a \to \ell s b)) \to (\forall a b. (\forall s. \ell s a \to \ell s b)) \to \ell s (a,b) \to \ell s a$ such that lift $f_{\ell} = h \ell$ unlift, and thus `Lens` is abstract in `lift f_{\ell}`.

Now the compositional reasoning of well-behavedness extends to lens functions; we can use a logical relation (Reynolds 1983) to characterize well-behavedness for higher-order functions. As an instance, we can state that functions of type $\forall s. \text{Lens } s A \to \text{Lens } s B$ are well-behavedness preserving as follows.

**Theorem 1.** Let $f :: \forall s. \text{Lens } s A \to \text{Lens } s B$ be a function in which `Lens` is abstract. Suppose that only well-behaved lenses are passed to `lift` during evaluation. Then, $f$ preserves well-behavedness, and thus `unlift` $f$ is well-behaved.

The functions lift $f_{\ell} \circ \text{lift } f_{\ell}$ and twice (lift $f_{\ell}$) are examples of $f$ in this theorem. Notice that we can use `unlift` in the definition of $f$; `lift` (`unlift` (lift $f_{\ell}$)) is also a function in
which \textit{Lens} is abstract and has a type \(\forall s.\text{Lens}\ s\ (A, B) \to \text{Lens}\ s\ A\). We shall omit the proof of Theorem 1 because it can be proved similarly to Theorem 4 and 6. The condition on lift in Theorem 1, which is also assumed in Theorems 4 and 6, essentially asserts that (the denotation of) lift only takes well-behaved lenses, which will be used in the proof of Theorem 6 in Section 8.

Another consequence of having abstract \textit{Lens} is that lift is now surjective (and \textit{unlift} is now injective).

\textbf{Lemma 1.} Let \(f\) be a function of type \(\forall s.\text{Lens}\ s\ A \to \text{Lens}\ s\ B\) in which \textit{Lens} is abstract. Then \(f\ \ell = f\ \text{id}_A\ \ell\ \ell\) holds for all \(\ell :: \text{Lens}\ s\ A\).

Although this lemma is key to prove the bijectivity of lift/unlift and ensures the naturality of \(f\), which is mentioned in Yoneda lemma (Section 2.4), our system does not rely on the surjectivity of lifting functions for correctness: injectivity alone is sufficient. As a matter of fact, the bijectivity property does not hold when we extend lifting to \(n\)-ary lenses in Section 3. Therefore, we delay the largish proof of this lemma to Appendix A, so as not to disrupt the flow of the paper.

\textbf{Theorem 2.} For any \(f :: \forall s.\text{Lens}\ s\ A \to \text{Lens}\ s\ B\) in which \textit{Lens} is abstract, lift \((\text{unlift}\ f) = f\) holds.

In the rest of this paper, we always assume abstract \textit{Lens} unless specially mentioned otherwise.

\section*{2.3 Guaranteeing Abstraction}

Theorem 1 requires the condition that \textit{Lens} is abstract in \(f\), which can be enforced by using abstract types through module systems. For example, in Haskell, we can define the following module to abstract \textit{Lens}:

\begin{verbatim}
module AbstractLens (Lens_abs, lift_abs, unlift_abs) where
  newtype Lens_abs a b = Lens_abs { unLens_abs :: Lens a b }
  lift_abs :: Lens a b \to (\forall s.\text{Lens}\ s\ a \to \text{Lens}\ s\ b)
  lift_abs \ell = \lambda x \to \text{Lens}\ s\ (\text{lift}\ \ell\ (\text{unLens}\ s\ x))
  unlift_abs :: (\forall s.\text{Lens}\ s\ a \to \text{Lens}\ s\ b) \to \text{Lens}\ a\ b
  unlift_abs f = \text{unlift}\ (\text{unLens}\ s\ \circ\ f\ \circ\ \text{Lens}\ s\ abs)
\end{verbatim}

Outside the module \textit{AbstractLens}, we can use \textit{lift_abs}, \textit{unlift_abs} and type \textit{Lens_abs} itself, but not the constructor of \textit{Lens_abs}. Thus the only way to access data of type \textit{Lens} is through \textit{lift_abs} and \textit{unlift_abs}.

\section*{2.4 Categorical Notes}

As mentioned earlier, our idea of mapping \textit{Lens} \(A\ B\) to \(\forall s.\text{Lens}\ s\ A \to \text{Lens}\ s\ B\) is based on the Yoneda lemma in category theory (Mac Lane 1998, Section III.2). Since our purpose of this paper is not categorical formalization, we briefly introduce an analogue of the Yoneda lemma that is enough for our discussion.
Theorem 3 (An Analogue of the Yoneda Lemma (Mac Lane 1998, Section III.2)). The pair of functions \((\text{lift}, \text{unlift})\) is a bijection between

- \(\{\ell :: \text{Lens } A \rightarrow B\}\), and
- \(\{f :: \forall s. \text{Lens } s \rightarrow A \rightarrow \text{Lens } s \rightarrow B | f x \circ \delta y = f (x \circ \delta y)\}\).

The condition \(f x \circ \delta y = f (x \circ \delta y)\) is required to make \(f\) a natural transformation between functors \(\text{Lens } (-)\) and \(\text{Lens } (-)\). Here, the contravariant functor \(\text{Lens } (-)\) maps a lens \(\ell\) of type \(\text{Lens } Y X\) to a function \((\lambda y \rightarrow y \circ \delta \ell)\) of type \(\text{Lens } X A \rightarrow \text{Lens } Y A\). Note that \(f x \circ \delta y = f (x \circ \delta y)\) is equivalent to \(f x = f \circ \text{id}_L \circ \delta x\). Thus the naturality condition implies Theorem 2 (through Lemma 1), and vice versa. That is, Theorem 3 is nothing but Proposition 1 and Theorem 2 put together.

It sounds contradictory, but there are no higher-order lenses in a categorical sense. Recall that the set of (not-necessarily-well-behaved) lenses forms a category. This category of lenses is monoidal (Hofmann et al. 2011), but is believed to be not closed (Rajkumar et al. 2013) and have no higher-order lenses. Our discussion does not conflict with this fact. What we state is that, for any \(s\), \((\text{Lens } s A, \text{Lens } s B) \rightarrow \text{Lens } s C\) is isomorphic to \(\text{Lens } s A \rightarrow (\text{Lens } s B \rightarrow \text{Lens } s C)\), where \(s\) is quantified globally; the standard curry and uncurry are the required bijections.

Also note that \(\text{Lens } s (-)\) is a functor that maps a lens \(\ell\) to a function \(\text{lift } \ell\). It is not difficult to check that \(\text{lift } \circ \text{lift } y = \text{lift } (x \circ \delta y)\) and \(\text{lift } (\text{id}_L :: \text{Lens } s A) = (\text{id} :: \text{Lens } s A \rightarrow \text{Lens } s A)\).

3 Lifting n-ary Lenses and Flexible Duplication

So far we have presented a system that lifts lenses to functions, manipulates the functions, and then “unlifts” the results to construct composite lenses. One example is \(\text{fstTri}_L\) from Section 2 reproduced below.

\[
\begin{align*}
\text{fstTri}_L &:: \text{Lens } ((a, b), (c, a)) \\
\text{fstTri}_L & = \text{unlift } (\text{lift } \text{fst}_L \circ \text{lift } \text{fst}_L)
\end{align*}
\]

Astute readers may have already noticed the type \(\text{Lens } ((a, b), (c, a))\) which is subtly distinct from \(\text{Lens } (a, b, c) a\). One reason for this is with the definition of \(\text{fstTri}_L\). which consists of the composition of lifted \(\text{fs}_{L}\) s. But more fundamentally it is the type of lift \((\forall s. \text{Lens } s \rightarrow \text{Lens } s y)\), which treats \(x\) as a black box, that has prevented us from rearranging the tuple components.

Let’s illustrate the issue with an even simpler example that goes directly to the heart of the problem.

\[
\begin{align*}
\text{swap}_L &:: \text{Lens } (a, b) (b, a) \\
\text{swap}_L & = \ldots
\end{align*}
\]

Following the programming pattern developed so far, we would like to construct this lens with the familiar unidirectional function \(\text{swap } :: (a, b) \rightarrow (b, a)\). But since lift only produces unary functions of type \(\forall s. \text{Lens } s A \rightarrow \text{Lens } s B\), despite the fact that \(A\) and \(B\) are actually pair types here, there is no way to compose \(\text{swap}\) with the resulting lens function. If we use the intuition developed in Section 2.1 that a lens of type \(\text{Lens } s A\) represents an updatable datum
of type \(A\), lift treats a pair (indeed any data structure) as a single datum. What we really want here is a pair of functions \(\text{lift}^2::\text{Lens}(a,b)\ c\rightarrow(\forall s.\ (\text{Lens}\ s\ a,\ \text{Lens}\ s\ b)\rightarrow\text{Lens}\ s\ c)\) and \(\text{unlift}^2:(\forall s.\ (\text{Lens}\ s\ a,\ \text{Lens}\ s\ b)\rightarrow\text{Lens}\ s\ c)\rightarrow\text{Lens}(a,b)\ c\), which are able to go into the pair structure and create separate updatable data that can be manipulated by functions like \text{swap} as:

\[
\text{swap}_L::\text{Lens}(a,b)(b,a)\\\text{swap}_L = \text{unlift}^2(\text{lift}^2\text{id}_L\circ\text{swap})
\]

In this section, we will see how such a \(\text{lift}^2/\text{unlift}^2\) pair is defined (with slightly different types for the reason that will be discussed in Section 3.1), and show how the idea of having \(\text{lift}^2/\text{unlift}^2\) is related to \textit{Applicative} in Haskell (McBride & Paterson 2008; Paterson 2012).

### 3.1 Caveats of the Duplication Lens

The key of binary lifting is the ability to split a pair and have separate lenses applied to each component. This is achieved via function \((\otimes)\), pronounced “split”.

\[
(\otimes)::\text{Eq}\ s\Rightarrow\text{Lens}\ s\ a\rightarrow\text{Lens}\ s\ b\rightarrow\text{Lens}\ s\ (a,b)\\x\otimes y = (x\otimes y)\circ\text{dup}_L
\]

where \((\otimes)\) is a lens combinator that combines two lenses applying to each component of a pair (Foster et al. 2007):

\[
(\otimes)::\text{Lens}\ a\ a'\rightarrow\text{Lens}\ b\ b'\rightarrow\text{Lens}\ (a,b)(a',b')\\(\text{Lens}\ \text{get}_1\ \text{put}_1)\otimes(\text{Lens}\ \text{get}_2\ \text{put}_2) = (\lambda(a,b)\rightarrow(\text{get}_1\ a,\text{get}_2\ b))(\lambda(a',b')\rightarrow(\text{put}_1\ a\ a',\text{put}_2\ b\ b'))
\]

With \((\otimes)\) we can define the lifting of binary lenses as below.

\[
\text{lift}^2::\text{Lens}(a,b)\ c\rightarrow(\forall s.\ (\text{Lens}\ s\ a,\ \text{Lens}\ s\ b)\rightarrow\text{Lens}\ s\ c)\\\text{lift}^2\ell(x,y) = \ell(x\otimes y)
\]

The class constraint \(\text{Eq}\ s\) in the type of \((\otimes)\) comes from the use of duplication lens \(\text{dup}_L\) (also known as \textit{copy} elsewhere (Foster et al. 2007)) defined as below. For simplicity, we assume that \((\equiv)\) represents observational equivalence.

\[
\text{dup}_L::\text{Eq}\ s\Rightarrow\text{Lens}\ s\ (s,s)\\\text{dup}_L = \text{Lens}(\lambda s\rightarrow(s,s))(\lambda s\rightarrow(\text{checkEq}\ s\ t))\\\text{where}\ \text{checkEq}\ s\ t\ |\ s\equiv t = s\ --\ This\ will\ cause\ a\ problem\ later.
\]

Despite being fitting type-wise, this definition of \(\text{dup}_L\) causes a serious execution issue. We would like to use the following definition as \(\text{lift}^2\)’s left inverse.

\[
\text{unlift}^2:(\forall s.\ (\text{Lens}\ s\ a,\ \text{Lens}\ s\ b)\rightarrow\text{Lens}\ s\ c)\rightarrow\text{Lens}(a,b)\ c\\\text{unlift}^2f = f(\text{fst}_L,\text{snd}_L)
\]

But \(\text{unlift}^2\circ\text{lift}^2\) does not result in identity:

\[
(\text{unlift}^2\circ\text{lift}^2)\ell\\= \{\text{definition unfolding & }\beta\text{-reduction}\}
\]
Applicative Bidirectional Programming

\[ \ell \circ (\text{fst} \otimes \text{snd}) \]
\[ = \{ \text{unfolding } \otimes \} \]
\[ \ell \circ (\text{fst} \otimes \text{snd}) \circ \text{dup}_L \]
\[ = \{ \text{definition unfolding } \} \]
\[ \ell \circ \text{block}_L \text{ where} \]
\[ \text{block}_L = \text{Lens id} \]
\[ (\lambda s \, v \rightarrow \text{if } s \approx v \text{ then } v \text{ else } \perp) \]

Lens \text{block}_L is not a useful lens because it blocks any update to the view. Consequently any lenses composed with it become useless too. The reason for the failure is that \text{dup}_L demands the duplicated copies to remain equal amid updates, which will not hold because the purpose of the duplication is to create separate updatable data.

### 3.2 Flexible and Safe Duplication by Tagging

If we look at the lens \text{dup}_L in isolation, there seems to be no way out. The two duplicated values have to remain equal for the bidirectional laws to hold. However, if we consider the context in which \text{dup}_L is applied, there is more room for maneuver. Let us consider the lifting function \text{lift}_2 again, and how \text{put dup}_L, which rejects the update above, works in the execution of \text{put (unlift}_2 ((\text{lift}_2 \text{id}_L))).

\[ \text{put (unlift}_2 ((\text{lift}_2 \text{id}_L)) \] (1, 2) (3, 4)
\[ = \{ \text{simplification } \} \]
\[ \text{put ((fst}_L \otimes \text{snd}_L) \circ \text{dup}_L) \] (1, 2) (3, 4)
\[ = \{ \text{definition unfolding } \} \]
\[ \text{put dup}_L \] (1, 2) \text{put fst}_L \] (1, 2) \text{put snd}_L \] (1, 2) (3, 4)
\[ = \{ \text{β-reduction } \} \]
\[ \text{put dup}_L \] (1, 2) ((3, 2), (1, 4))

The last call to \text{put dup}_L above will fail because (3, 2) \not\approx (1, 4). But if we look more carefully, there is no reason for this behavior: \text{lift}_2 \text{id}_L should be able to update the two elements of the pair independently. Indeed in the \text{put} execution above, relevant values to the view change as highlighted by underlining are only compared for equality with irrelevant values. That is to say, we should be able to relax the equality check in \text{dup}_L and update the old source (1, 2) to (3, 4) without violating bidirectional laws.

To achieve this, we tag the values according to their relevance to view updates (Mu et al. 2004).

\textbf{data} \text{Tag} a = U \{ \text{unTag} :: a \} \mid O \{ \text{unTag} :: a \}

Tag \text{U} (representing Updated) means the tagged value may be relevant to the view update and \text{O} (representing Original) means the tagged value must not be relevant to the view update. The idea is that \text{O}-tagged values can be altered without violating the bidirectional laws, as the new \text{dup}_L below.

\text{dup}_L :: \text{Poset} s \Rightarrow \text{Lens } (s, s)
\text{dup}_L = \text{Lens} (\lambda s \rightarrow (s, s)) (\lambda \_ \rightarrow s \_ \_)

Here, \text{Poset} is a type class for partially-ordered sets that has a method (\_\_) (pronounced as “lub”) to compute least upper bounds.
Kazutaka Matsuda and Meng Wang

\[
\text{class } \text{Poset } s \text{ where } (\gamma) : s \to s \to s
\]

We require that \((\gamma)\) must be associative, commutative and idempotent; but unlike a semilattice, \((\gamma)\) can be partial. Tagged elements and their (nested) pairs are ordered as follows.

\[
\text{instance } \text{Eq } a \Rightarrow \text{Poset } (\text{Tag } a)
\text{ where }
\]

\[
\begin{align*}
(O ) \gamma (U t) & = U t \\
(U s) \gamma (O ) & = U s \\
(O s) \gamma (O t) | s t & = O s \quad \text{-- The check } s t \text{ never fails.} \\
(U s) \gamma (U t) | s t & = U s \quad \text{-- In contrast, this check can fail.}
\end{align*}
\]

\[
\text{instance } (\text{Poset } a, \text{Poset } b) \Rightarrow \text{Poset } (a, b)
\text{ where }
\]

\[
(a, b) \gamma (a', b') = (a \gamma a', b \gamma b')
\]

We also introduce the following type synonym for brevity.\(^1\)

\[
\text{type } L s a = \text{Poset } s \Rightarrow \text{Lens } s a
\]

As we will show later, the move from \(\text{Lens}\) to \(L\) will have implications on well-behavedness.

Accordingly, we change the types of \((\otimes), \text{lift and lift}_2\) as below (notice that due to the change of \(\text{dup}_L\) the behavior of \(\text{lift}_2\) is changed accordingly)

\[
\begin{align*}
(\otimes) & \:: L s a \to L s b \to L s (a, b) \\
\text{lift} & \:: \text{Lens } a b \to (\forall s. L s a \to L s b) \\
\text{lift}_2 & \:: \text{Lens } (a, b) c \to (\forall s. (L s a, L s b) \to L s c)
\end{align*}
\]

and adapt the definitions of \(\text{unlift}\) and \(\text{unlift}_2\) to properly handle the newly introduced tags.

\[
\begin{align*}
\text{unlift} & \:: \text{Eq } a \Rightarrow (\forall s. L s a \to L s b) \to \text{Lens } a b \\
\text{unlift } f & = f id'_L \circ \text{tag}_L \\
id'_L & \:: L (\text{Tag } a) a \\
id'_L & = \text{Lens } \text{unTag } (\text{const } U) \\
\text{tag}_L & \:: \text{Lens } a (\text{Tag } a) \\
\text{tag}_L & = \text{Lens } O (\text{const } \text{unTag})
\end{align*}
\]

\[
\begin{align*}
\text{unlift}_2 & \:: (\text{Eq } a, \text{Eq } b) \Rightarrow (\forall s. (L s a, L s b) \to L s c) \to \text{Lens } (a, b) c \\
\text{unlift}_2 f & = f (\text{fst}_L', \text{snd}_L') \circ \text{tag}_2_L \\
\text{fst}_L' & \:: L (\text{Tag } a, \text{Tag } b) a \\
\text{fst}_L' & = \text{Lens } (\lambda (a, _) \to \text{unTag } a) (\lambda (b) a \to (U a, b)) \\
\text{snd}_L' & \:: L (\text{Tag } a, \text{Tag } b) b \\
\text{snd}_L' & = \text{Lens } (\lambda (b) \to \text{unTag } b) (\lambda (a, b) \to (a, U b)) \\
\text{tag}_2_L & \:: \text{Lens } (a, b) (\text{Tag } a, \text{Tag } b) \\
\text{tag}_2_L & = \text{tag}_L \odot \text{tag}_L
\end{align*}
\]

We need to change \(\text{unlift}\), though no duplication is needed in the unary case, because the function may be applied to functions calling \(\text{lift}_2\) internally. The definitions are a bit

\(^1\) Actually, we will have to use \texttt{newtype} for the code in this paper to pass GHC 7.8.3’s type checking. We take a small deviation from GHC Haskell here in favor of brevity.
Thus, we have proved that lift. We prove the statement with the following calculation.

**Proposition 4.** unlift₂ (lift₂ ℓ) = ℓ holds for all lenses ℓ :: Lens (A, B) C.

**Proof**

We prove the statement with the following calculation.

\[
\text{unlift}_2 (\text{lift}_2 \ell) = \ell = \text{definition unfolding & } \beta\text{-reduction} \quad \ell \odot (\text{fst}_2 \odot \text{snd}_2) \odot \text{tag}_2 \ell = \ell = \text{unfolding } (\odot) \quad \ell \odot (\text{fst}_2 \odot \text{snd}_2) \odot \text{dup}_2 \odot \text{tag}_2 \ell = \ell = \text{definitions of } \text{fst}_2 \odot \text{snd}_2 \odot \text{tag}_2 \ell = \ell = \text{id}_L \quad (1) \quad \ell
\]

We prove the statement labeled (1) by showing get ((\text{fst}_2 \odot \text{snd}_2) \odot \text{dup}_2 \odot \text{tag}_2 \ell) (a, b) = (a, b) and put ((\text{fst}_2 \odot \text{snd}_2) \odot \text{dup}_2 \odot \text{tag}_2 \ell) (a, b) (a', b') = (a', b'). Since the former property is easy to prove, we only show the latter here.

\[
\text{put} ((\text{fst}_2 \odot \text{snd}_2) \odot \text{dup}_2 \odot \text{tag}_2 \ell) (a, b) (a', b') = \text{definition unfolding & } \beta\text{-reduction} \quad \text{put} \text{tag}_2 \ell (a, b) \odot \text{put} ((\text{fst}_2 \odot \text{snd}_2) \odot \text{dup}_2) (O a, O b) (a', b') = \text{definition unfolding & } \beta\text{-reduction} \quad \text{put} \text{tag}_2 \ell (a, b) \odot \text{put} \text{dup}_2 (O a, O b) (U a', O b) (O a, U b') = \text{definitions of } \text{fst}_2 \odot \text{snd}_2 \odot \text{tag}_2 \ell = \text{definition of } \text{dup}_2 \quad \text{put} \text{tag}_2 \ell (a, b) (U a', U b') = \text{definition of } \text{tag}_2 \ell \quad \text{put} \text{tag}_2 \ell (U a', b) (U b') = \text{definition of } \text{tag}_2 \ell \quad (a', b')
\]

Thus, we have proved that lift₂ is injective.

We can recreate \text{fst}_L and \text{snd}_L with unlift₂, which is rather reassuring.

**Proposition 5.** \text{fst}_L = \text{unlift}_2 \text{fst} and \text{snd}_L = \text{unlift}_2 \text{snd}.

**Example 1 (swap).** Lens \text{swap}_L as seen in the beginning of this section can be defined as follows

\[
\text{swap}_L :: (Eq a, Eq b) \Rightarrow \text{Lens } (a, b) (b, a) \\
\text{swap}_L = \text{unlift}_2 (\text{lift}_2 \text{id}_L \odot \text{swap})
\]

and it behaves as expected.

Kazutaka Matsuda and Meng Wang

\[
\text{put swap}_L (1, 2) (4, 3)
\]
\[
= \{ \text{unfold definitions} \}
\]
\[
\text{put} \ ((\text{snd}_L \odot \text{fst}_L) \odot \text{dup}_L \odot \text{tag}_2)_L (1, 2) (4, 3)
\]
\[
= \{ \text{simplifications} \}
\]
\[
\text{put tag}_2_L (1, 2) \$ \text{put dup}_L (O 1, O 2) \$ (\text{put snd}_L (O 1, O 2) 4, \text{put fs}_L (O 1, O 2) 3)
\]
\[
= \{ \text{definition of fs}_L \text{ and snd}_L \}
\]
\[
\text{put tag}_2_L (1, 2) \$ \text{put dup}_L (O 1, O 2) ((O 1, U 4), (U 3, O 2))
\]
\[
= \{ \text{definitions of dup}_L \text{ and tag}_2_L \}
\]
\[
(3, 4)
\]

It is worth mentioning that (\(\otimes\)) is the base for “splitting” and “lifting” tuples of arbitrary arity. For example, the triple case is as follows.

\[
\text{split}_3 :: (L s a, L s b, L s c) \Rightarrow L s (a, b, c)
\]
\[
\text{split}_3 (x, y, z) = \text{lift flatten}_L (x \otimes y \otimes z)
\]
\[
\quad \text{where flatten}_L :: \text{Lens} ((a, b), c) (a, b, c)
\]
\[
\quad \quad \quad \quad \text{flatten}_L = \text{Lens} (\lambda (x, y, z) \mapsto (x, y, z))
\]
\[
\quad \quad \quad \quad \quad \quad \quad \quad \quad (\lambda (x, y, z) \mapsto ((x, y), z))
\]
\[
\quad \quad \quad \quad \quad \quad \quad \quad \quad \text{lift}_3 \ell t = \text{lift } \ell \ (\text{split}_3 \ t)
\]

For unlifts, we additionally need n-ary versions of projection and tagging functions. But they are straightforward to define. In the above definition of \(\text{split}_3\), we have decided to nest to the left in the intermediate step. This choice is not essential.

\[
\text{split}_3' (x, y, z) = \text{lift flatten}_L (x \otimes (y \otimes z))
\]
\[
\quad \text{where flatten}_L :: \text{Lens} (a, (b, c)) (a, b, c)
\]
\[
\quad \quad \quad \quad \text{flatten}_L = \text{Lens} (\lambda (x, y, z) \mapsto (x, y, z))
\]
\[
\quad \quad \quad \quad \quad \quad \quad \quad \quad (\lambda (x, y, z) \mapsto (x, y), z))
\]

The two definitions \(\text{split}_3\) and \(\text{split}_3'\) coincide. That is, (\(\otimes\)) is associative up to isomorphism.

To complete the picture, the nullary lens function

\[
\text{unit} :: \forall s. L s ()
\]
\[
\text{unit} = \text{Lens} (\lambda教会 \mapsto ()) (\lambda s () \mapsto s)
\]
is the unit for (\(\otimes\)). Theoretically \((L s (-), \otimes, \text{unit})\) forms a lax monoidal functor (Mac Lane 1998, Section XI.2) under certain conditions (see Section 3.4). Practically, unit enables us to define the following combinator.

\[
\text{new} :: \text{Eq } a \Rightarrow a \Rightarrow \forall s. L s a
\]
\[
\text{new } a = \text{lift} (\text{Lens} \ (\text{const} a)) (\lambda (a' \mapsto \text{check } a a')) \text{ unit}
\]
\[
\quad \text{where}
\]
\[
\text{check } a a' = \text{if } a \equiv a' \text{ then } ()
\]
\[
\text{else error "Update on constant"}
\]

Function \(\text{new}\) lifts ordinary values into the bidirectional transformation system; but since the values are not from any source, they are not updatable. Nevertheless, this ability to lift
constant values is very useful in practice (Matsuda & Wang 2013, 2014), as we will see in the examples to come.

Note that now unlifts are no longer injective (even with abstract Lens); there exist functions that are not equivalent but coincide after unlifting. An example of such is the pair lift2 \(\text{fst}_L\) and \(\text{fst}\): while unlifting both functions results in \(\text{fst}_L\), they actually differ as \(\text{put} (\text{lift2} \text{fst}_L (\text{fst}_L' \text{snd}_L')) (O a, O b) c = (U c, U b)\) and \(\text{put} (\text{fst} (\text{fst}_L' \text{snd}_L')) (O a, O b) c = (U c, O b)\). Intuitively, \(\text{fst}\) knows that the second argument is unused, while \(\text{lift2} \text{fst}_L\) does not because \(\text{fst}_L\) is treated as a black box by \(\text{lift2}\). In other words, the relationship between the lifting/unlifting functions and the Yoneda Lemma discussed in Section 2 ceases to exist in this new context. Nevertheless, the counter-example scenario described here is contrived and will not affect practical programming in our framework.

Another side effect of this new development with tags is that the original bidirectional laws, i.e., the well-behavedness, are temporarily broken during the execution of \(\text{lift2}\) and unlift2 by the new internal functions \(\text{fst}_L', \text{snd}_L'\), \(\text{dup}_L\) and \(\text{tag}_L\). Consequently, we need a new theoretical development to establish the preservation of well-behavedness by the lifting/unlifting process.

### 3.3 Relevance-Aware Well-Behavedness

We have noted that the new internal functions \(\text{dup}_L, \text{fst}_L', \text{snd}_L'\) and \(\text{tag}_L\) are not well-behaved, for different reasons. For functions \(\text{fst}_L'\) and \(\text{snd}_L'\), the difference from the original versions \(\text{fst}_L\) and \(\text{snd}_L\) is only in the additional wrapping/unwrapping that is required due to the introduction of tags. As a result, as long as these functions are used in an appropriate context, the bidirectional laws are expected to hold. But for \(\text{dup}_L\) and \(\text{tag}_L\), the new definitions are more defined in the sense that some originally failing executions of \(\text{put}\) are now intentionally turned into successful ones. For this change in semantics, we need to adapt the laws to allow temporary violations and yet still establish well-behavedness of the resulting bidirectional transformations in the end. For example, we still want \(\text{unlift}_2 f\) to be well-behaved for any \(f : \forall s. (L s A, L s B) \rightarrow L s C\), as long as the lifting functions are applied to well-behaved lenses.

#### 3.3.1 Relevance-Ordering and Lawful Duplications

Central to the discussion in this and the previous subsections is the behavior of \(\text{dup}_L\). To maintain safety, unequal values as duplications are only allowed if they have different tags (i.e., one value must be irrelevant to the update and can be discarded). We formalize such a property with the partial ordering between tagged values. Let us write \((\preceq)\) for the partial order induced from \(\succeq\): that is, \(s \preceq t\) if \(s \succeq t\) is defined and equal to \(t\). One can see that \((\preceq)\) is the reflexive closure of \(O s \preceq U t\). The definition of \((\preceq)\) is extended to \((n\text{-ary})\) containers element-wise; for example, \((s_1, s_2) \preceq (t_1, t_2)\) if and only if \(s_1 \preceq t_1\) and \(s_2 \preceq t_2\). Nesting of tags is not allowed. We write \(\uparrow s\) for a value obtained from \(s\) by replacing all \(O\) tags with \(U\) tags. Trivially, we have \(s \preceq \uparrow s\). But there exists \(s'\) such that \(s \preceq s'\) and \(s' \neq \uparrow s\), unless \(s\) contains only \(U\) tags.

Now we can define a variant of well-behavedness local to the \(U\)-tagged elements.
Definition 2 (Local Well-Behavedness). Let $A$ be a type associated with $(\preceq)$. A bidirectional transformation $\ell :: LAB$ is called locally well-behaved if the following four conditions hold.

- (Forward Tag-Irrelevance) If $v = \text{get } \ell s$, then for all $s'$ such that $\uparrow s' = \uparrow s$, $v = \text{get } \ell s'$ holds.
- (Backward Inflation) For all minimal (with respect to $\preceq$) $s$, if $\text{put } \ell s v$ succeeds as $s'$, then $s \preceq s'$.
- (Local Acceptability) For all $s, s \preceq \text{put } \ell s (\text{get } \ell s) \preceq \uparrow s$.
- (Local Consistency) For all $s$ and $v$, assuming $\text{put } \ell s v$ succeeds as $s'$, then for all $s''$ with $s' \preceq s''$, $\text{get } \ell s'' = v$ holds.

In the above, tags introduced for the flexible behavior of put must not affect the behavior of get: $\uparrow s' = \uparrow s$ means that $s$ and $s'$ are equal if tags are ignored. The property backward inflation states that put puts $U$-tags to all the updated elements, and thus $O$-tagged elements in the put result are kept unchanged, which will be used to show the naturality of $(\otimes)$ in Section 3.4. The property local-acceptability is similar to acceptability, except that $U$-tags are allowed to change to $U$-tags. The property local consistency is stronger than consistency in the sense that get must map all values sharing the same $U$-tagged elements with $s'$ to the same view. The idea is that $O$-tagged elements in $s'$ are not connected to the view $v$, and thus changing them will not affect $v$. In this sense, $O$-tagged values must not be relevant to the view. A similar reasoning applies to backward inflation stating that source elements changed by put will have $U$-tags. Note that in this definition of local well-behavedness, tags are assumed to appear only in the sources. As a matter of fact, only $\text{dup}_L$ and $\text{tag}_L/\text{tag}_2$ introduce tagged views (and actually they are not locally well-behaved); but they are always precomposed when used, as shown in the definitions of lift and unlift.

We have the following compositional properties for local well-behavedness.

Lemma 2. The following properties hold for bidirectional transformations $x$ and $y$ with appropriate types.

- If $x$ is well-behaved and $y$ is locally well-behaved, then lift $x \otimes y$ is locally well-behaved.
- If $x$ and $y$ are locally well-behaved, $x \otimes y$ is locally well-behaved.
- If $x$ and $y$ are locally well-behaved, $x \otimes \text{tag}_L$ and $y \otimes \text{tag}_L$ are well-behaved.

Proof

We only prove the second and third properties because it is straightforward to prove the first property.

The second property. We first show local acceptability.

$$\text{put } ((x \otimes y) \otimes \text{dup}_L) s (\text{get } ((x \otimes y) \otimes \text{dup}_L) s)$$

$$= \begin{cases} \text{simplification} & \text{put } \text{dup}_L s (\text{put } (x \otimes y) (s, s) (\text{get } (x \otimes y) (s, s))) \\ \text{by the local acceptability of } x \otimes y & \text{put } \text{dup}_L s (s', s'') \text{ where } s \preceq s' \preceq \uparrow s, s \preceq s'' \preceq \uparrow s \\ \text{by the definition of } \text{dup}_L \text{ and that } s' \otimes s'' \text{ is defined} & s' \otimes s'' \preceq \uparrow s \end{cases}$$
Applicative Bidirectional Programming

17

Note that, since \( s' \preceq s \) and \( s'' \preceq s \), it follows that \( s' \triangleright s'' \preceq s \).

Then, we prove local consistency. Assume that \( \text{put} ((x \odot y) \odot \text{dup}_L) s \) succeeds in \( s' \). Then, by the following calculation, we have \( s' = \text{put} x s_1 \triangleright \text{put} y s_2 \).

\[
\text{put} ((x \odot y) \odot \text{dup}_L) s \ (v_1, v_2) = \text{definition unfolding} \]
\[= \text{the forward tag-irrelevance of} \]
\[= \text{the local consistency of} \]
\[= \text{the local acceptability of} \]
\[= \text{the local consistency of} \]

Let \( s'' \) be a source such that \( s' \preceq s'' \). Then, we prove \( \text{get} ((x \odot y) \odot \text{dup}_L) s'' \) as follows.

\[
\text{get} ((x \odot y) \odot \text{dup}_L) s'' \ (v_1, v_2) = \text{definition unfolding} \]
\[= \text{the local consistency of} \]
\[= \text{the local acceptability of} \]
\[= \text{the local consistency of} \]

Note that we have \( \text{put} x s_1 \preceq s' \preceq s'' \) and \( \text{put} y s_2 \preceq s' \preceq s'' \) by the definition of \( \triangleright \).

Forward tag-irrelevance and backward inflation are straightforward.

The third property. First, we prove acceptability.

\[
\text{put} \ (x \odot \text{tag}_L) \ (s_1, s_2) \ (\text{get} \ (x \odot \text{tag}_L) \ (s_1, s_2)) \]
\[= \text{unfolding} \]
\[= \text{the local acceptability of} \]
\[= \text{the local consistency of} \]

The proof of the acceptability of \( y \odot \text{tag}_L \) is similar.

Next, we prove consistency. Assume that \( (s_1', s_2') = \text{put} \ (x \odot \text{tag}_L) \ (s_1, s_2) \ v \). Then, it must be the case when there are \( \text{tag}_1 \) and \( \text{tag}_2 \) such that \( \langle \text{tag}_1, s_1', \text{tag}_2, s_2' \rangle = \text{put} x \ (O s_1, O s_2) \ v \) where \( \text{tag}_i \) is either \( O \) or \( U \) for \( i = 1, 2 \). Here, we have \( (O s_1', O s_2') \preceq (\text{tag}_1, s_1', \text{tag}_2, s_2') \). Then, we have:

\[
\text{get} \ (x \odot \text{tag}_L) \ (s_1', s_2') = \text{unfolding} \]
\[= \text{the forward tag-irrelevance of} \]
\[= \text{the local consistency of} \]
\[= \text{the local consistency of} \]

\( v \)
The proof of the consistency of $\gamma \circ \text{tag}_L$ is similar.

**Corollary 1.** The following properties hold.

- **lift** $\ell :: \forall s. L s A \rightarrow L s B$ preserves local well-behavedness, if $\ell :: \text{Lens} A B$ is well-behaved.
- **lift** $\ell :: \forall s. (L s A, L s B) \rightarrow L s C$ preserves local well-behavedness, if $\ell :: \text{Lens} (A, B) C$ is well-behaved.

Similar to the case in Section 2, compositional reasoning of well-behavedness requires the lens type $L$ to be abstract.

**Definition 3 (Abstract Nature of $L$).** We say $L$ is abstract in $f :: \tau$ if there is a polymorphic function $h$ of type

$$\forall \ell. (\forall a b. \text{Lens} a b \rightarrow (\forall s \ell s a \rightarrow \ell s b))$$

$$\rightarrow (\forall a b. (\forall s \ell s a \rightarrow \ell s b) \rightarrow \text{Lens} a b)$$

$$\rightarrow (\forall s \ell s ())$$

$$\rightarrow (\forall a b. \ell s a \rightarrow \ell s (a, b))$$

$$\rightarrow (\forall a b c. (\forall s, (\ell s a, \ell s b) \rightarrow \ell s c) \rightarrow \text{Lens} (a, b) c)$$

$$\rightarrow \tau'$$

satisfying $f = h \text{ lift unlift unit (\otimes)} \text{ unlift}_2$ and $\tau' = \tau[\ell/L]$.

Then, we obtain the following properties from the free theorems (Voigtländer 2009b; Wadler 1989).

**Theorem 4.** Let $f$ be a function of type $\forall s. (L s A, L s B) \rightarrow L s C$ in which $L$ is abstract. Then, $f (x, y)$ is locally well-behaved if $x$ and $y$ are also locally well-behaved, assuming that only well-behaved lenses are passed to lift during evaluation.

We omit the proof because we will prove the more involved version, Theorem 6, in Section 8.

**Proposition 6.** $\text{fst}_L$ and $\text{snd}_L$ are locally well-behaved.

**Corollary 2.** Let $f$ be a function of type $\forall s. (L s A, L s B) \rightarrow L s C$ in which $L$ is abstract. Then, $\text{unlift}_2 f$ is well-behaved, assuming that only well-behaved lenses are passed to lift during evaluation.

### 3.4 Categorical Notes

Recall that $\text{Lens} S (\_)$ is a functor from the category of lenses to the category of sets and (total) functions, which maps $\ell :: \text{Lens} A B$ to lift $\ell :: \text{Lens} S A \rightarrow \text{Lens} S B$ for any $S$. In the case that $S$ is tagged and thus partially ordered, $(L S (\_), \otimes, \text{unit})$ forms a lax monoidal functor, under the following conditions.

- $(\otimes)$ must be natural, i.e., $(\text{lift} f x) \otimes (\text{lift} g y) = \text{lift} (f \circ g) (x \otimes y)$ for all $f, g, x$ and $y$ with appropriate types.
- split$_3$ and split$_3'$ coincide.
- lift $\text{elimUnit}_L$ (unit $\circ x) = x$ must hold where $\text{elimUnit}_L :: \text{Lens} (\_), a \rightarrow a$ is the bidirectional version of elimination of $(\_)$, and so does its symmetric version.
Intuitively, the second and the third conditions state that the mapping must respect the monoid structure of products, with the former concerning associativity and the latter concerning the identity elements. The first and second conditions above hold without any additional assumptions, whereas the third condition, which reduces to $s \equiv \text{put } x \ s \ v = \text{put } x \ s \ v$, is not necessarily true if $s$ is not minimal (if $s$ is minimal, this property holds by backward inflation—this is why we considered the backward inflation property). Recall that minimality of $s$ implies that $s$ can only have $O$-tags. To get around this restriction, we take $\mathcal{L} \mathcal{S} A$ as a quotient set of $\text{Lens } \mathcal{S} A$ by the equivalence relation $\equiv$ defined as $x \equiv y$ if $\text{get } x = \text{get } y \land \text{put } x \ s = \text{put } y \ s$ for all minimal $s$. This equivalence is preserved by manipulations of $L$-data; that is, the following holds for $x, y, z$ and $w$ with appropriate types.

- $x \equiv y$ implies $\text{lift } \ell \ x \equiv \text{lift } \ell \ y$ for any well-behaved lens $\ell$.
- $x \equiv y$ and $z \equiv w$ imply $x \otimes z \equiv y \otimes w$.
- $x \equiv y$ implies $x \circ \text{tag}_L = y \circ \text{tag}_L$ (or $x \circ \text{tag}_2L = y \circ \text{tag}_2L$).

Note that the above three cases cover the only ways to construct/destruct $L$ in $f$ when $L$ is abstract. The third condition says that this “coarse” equivalence ($\equiv$) on $L$ can be “sharpened” to the usual extensional equality ($=$) by $\text{tag}_L$ and $\text{tag}_2L$ in the uplifting functions. Thus, quotienting $L$ with $\equiv$, the three conditions hold, and thus we have the following theorem.

**Theorem 5.** $(\mathcal{L} \mathcal{S} (-), \otimes, \text{unit})$ forms a lax monoidal functor.

The fact that our framework forms a lax monoidal functor may suggest a connection to Haskell’s *Applicative* class (McBride & Paterson 2008; Paterson 2012), which shares the same mathematical structure. It is known that *Applicative* is exactly an endo lax monoidal functor (with strength) on the category of Haskell functions (Paterson 2012). However, it is not possible to structure our code with the *Applicative* class, because our functor is not endo and there are (believed to be) no exponentials in the category of lenses (Rajkumar et al. 2013). Nevertheless, one may consider the following classes similar to those in Rajkumar et al. (2013) (unlike their type classes we consider covariant functors instead of contravariant ones).

```haskell
class LFunctor f where
  lift :: Lens a b -> (f a -> f b)

class LFunctor f => LMonoidal f where
  unit :: f ()
  (⊗) :: f a -> f b -> f (a, b)
```

The laws for *LMonoidal* have already been discussed in Section 3.4. These classes have the following instance declarations.

```haskell
instance LFunctor (Lens s) where
  lift \ell x = \ell \circ x

instance Poset s => LMonoidal (Lens s) where
  unit = Lens (\_, x -> x) (\_, x -> s)
  x \otimes y = (x \circ y) \circ \text{dup}_L
```

We then can define $\text{lift}_2$ as:
lift_2 :: (a, b) c -> (\f. LMonoidal f \Rightarrow f a f b -> f c)
lift_2 \ell = \lambda (x, y) \rightarrow \text{lift } \ell (x \oplus y)

Now unlift and unlift_2 have the types Eq a \Rightarrow (\forall f. LMonoidal f \Rightarrow f a -> f b) -> Lens a b
and (Eq a, Eq b) \Rightarrow (\forall f. LMonoidal f \Rightarrow (f a f b) -> f c) -> Lens (a, b) c, respectively, while
their implementations are kept unchanged. Haskell programmers may prefer this class-based
interface, but it is more of a matter of taste.

4 Going Generic

In this section, we make the ideas developed in previous sections practical by extending the
technique to lists and other data structures.

4.1 Unlifting Functions on Lists

We have looked at how unlifting works for n-ary tuples in Section 3. And we now see how
the idea can be extended to lists. As a typical usage scenario, when we apply map to a lens
function lift_\ell, we will obtain a function of type map (lift_\ell) :: [L s A] -> [L s B]. But what
we really want is a lens of type Lens [A] [B]. The way to achieve this is to internally treat
length-n lists as n-ary tuples. This treatment effectively restricts us to in-place updates of
views (i.e., no change is allowed to the list structure); we will revisit this issue in more detail
in Section 6.1.

First, we can “split” lists by repeated pair-splitting, as follows.

\[ \text{split}_{\text{list}} :: [L s a] \rightarrow L s [a] \]
\[ \text{split}_{\text{list}} [] = \text{lift}\_\text{nil} \text{ unit} \]
\[ \text{split}_{\text{list}} (x:xs) = \text{lift}_2 \text{ cons}_{\text{list}} (x, \text{split}_{\text{list}} xs) \]
\[ \text{nil}_{\text{L}} = \text{Lens } (\lambda () \rightarrow []) (\lambda () [] \rightarrow ()) \]
\[ \text{cons}_{\text{L}} = \text{Lens } (\lambda (a, as) \rightarrow (a:as)) (\lambda (a':as') \rightarrow (a', as')) \]

The name of this function is inspired by \text{sequence} in Haskell. Then the lifting function is
defined straightforwardly.

\[ \text{lift}_{\text{list}} :: \text{Lens } [a] b \rightarrow \forall s. [L s a] \rightarrow L s b \]
\[ \text{lift}_{\text{list}} \ell xs = \text{lift } \ell (\text{split}_{\text{list}} xs) \]

Notice that we have \text{lift}_{\text{list}} id_{\text{L}} = \text{split}_{\text{list}}.

Tagged lists form an instance of \text{Poset}.

\[ \text{instance } \text{Poset } a \Rightarrow \text{Poset } [a] \text{ where} \]
\[ xs \succ ys = \text{if } \text{length } xs \succeq \text{length } ys \text{ then } \text{zipWith } (\succ) xs ys \]
\[ \text{else } \bot \text{ -- Unreachable in our framework} \]

Note that the requirement that xs and ys must have the same shape is made explicit above,
though it is automatically enforced by the abstract use of L in lifted functions.

The definition of unlift_{\text{list}} is a bit more involved. What we need to do is to turn every
element of the source list into a projection lens and apply the lens function f.
Applicative Bidirectional Programming

\[ \text{unlift}_{\text{list}} :: \forall a b. \text{Eq } a \Rightarrow (\forall s. [L s a] \rightarrow L s b) \rightarrow \text{Lens } [a] b \]

\[ \text{unlift}_{\text{list}} f = \text{Lens } (\lambda s \rightarrow \text{get } (\text{mkLens } s) s) (\lambda s \rightarrow \text{put } (\text{mkLens } s) s) \]

where

\[ \text{mkLens } s = f \left( \text{projs } (\text{length } s) \right) \circ \text{tagList}_L \]

\[ \text{tagList}_L = \text{Lens } (\map O) (\lambda ys \rightarrow \map \text{unTag } ys) \]

\[ \text{projs } n = \map \text{proj}_L [0..n-1] \]

\[ \text{proj}_L i = \text{Lens } (\lambda xs \rightarrow \text{unTag } (xs !! i)) (\lambda as \rightarrow \text{update } i (U a) as) \]

\[ \text{update} :: \text{Int } \rightarrow [a] \rightarrow [a] \]

\[ \text{update } 0 v (x : xs) = v : xs \]

\[ \text{update } i v (x : xs) = x : \text{update } (i - 1) v xs \]

Given that the need to inspect the length of the source leads to the separate definitions of \text{get} and \text{put} in the above, there might be worry that we may lose the guarantee of well-behavedness of the resulting lens. But this is not a problem here since the length of the source list is an invariant of the resulting lens. Similar to \text{lift2}, \text{lift3} is an injection with \text{unlift3} as its left inverse.

**Example 2 (Bidirectional \text{tail}).** Let us consider the function \text{tail}.

\[ \text{tail} :: [a] \rightarrow [a] \]

\[ \text{tail } (x : xs) = xs \]

A bidirectional version of \text{tail} is easily constructed by using \text{lssequence}_{\text{list}} and \text{unlift}_{\text{list}} as follows.

\[ \text{tail}_L :: \text{Eq } a \Rightarrow \text{Lens } [a] [a] \]

\[ \text{tail}_L = \text{unlift}_{\text{list}} (\text{lssequence}_{\text{list}} \circ \text{tail}) \]

The obtained lens \text{tail}_L supports all in-place updates, such as \text{put tail}_L ["a", "b", "c"] ["B", "C"] = ["a", "B", "c"]. In contrast, any change on list length will be rejected; specifically \text{nil}_L or \text{cons}_L in \text{lssequence}_{\text{list}} throws an error.

**Example 3 (Bidirectional \text{unlines}).** Let us consider a bidirectional version of \text{unlines} :: [\text{String}] \rightarrow \text{String} that concatenates lines, after appending a terminating newline to each. For example, \text{unlines} ["ab", "c"] = "ab\n\nc\n". In conventional unidirectional programming, one can implement \text{unlines} as follows.

\[ \text{unlines } [] = "" \]

\[ \text{unlines } (x : xs) = \text{catLine } x \text{ (unlines } xs) \]

\[ \text{catLine } x y = x ++ \"\n\" ++ y \]

To construct a bidirectional version of \text{unlines}, we first need a bidirectional version of \text{catLine}.

\[ \text{catLine}_L :: \text{Lens } (\text{String}, \text{String}) \text{ String} \]

\[ \text{catLine}_L = \]

\[ \text{Lens } (\lambda (s, t) \rightarrow s ++ \"\n\" ++ t) \]

\[ (\lambda (s, t) u \rightarrow \text{let } n = \text{length } (\text{filter } (== \"\n\") s) \]

\[ \text{update } i v (x : xs) = x : \text{update } (i - 1) v xs \]
\[i = \text{elemIndices} 'n' u \downarrow n\]
\[(s', t') = \text{splitAt} \ i \ u \in (s', \text{tail} \ t')\]

Here, \text{elemIndices} and \text{splitAt} are functions from \text{Data.List}: \text{elemIndices} \ c \ s \ returns \ the \ indices \ of \ all \ elements \ that \ are \ equal \ to \ c; \ \text{splitAt} \ i \ x \ returns \ a \ tuple \ where \ the \ first \ element \ is \ x's \ prefix \ of \ length \ i \ and \ the \ second \ element \ is \ the \ remainder \ of \ the \ list. \ Intuitively, \text{put catLine}_L(s, t) \ splits \ u \ into \ s' \ and \ "n" ++ t' \ so \ that \ s' \ contains \ the \ same \ number \ of \ newlines \ as \ the \ original \ s. \ For \ example, \text{put catLine}_L("a\nbc", "de") "A\nB\nC" = ("A\nB", "C").

Then, construction of a bidirectional version \text{unlines} is straightforward; we only need to replace "" with \text{new} "" and \text{catLine} with \text{lift2 catLine}_L, and to apply \text{unliftList} to obtain a lens.

\text{unlines}_L :: \text{Lens} [\text{String}] \text{String}
\text{unlines}_L = \text{unliftList} \text{unlines}_F
\text{unlines}_F :: \forall s. [\text{L} s \text{ String}] \rightarrow \text{L} s \text{ String}
\text{unlines}_F [] = \text{new} ""
\text{unlines}_F (x : xs) = \text{lift2} \text{catLine}_L (x, \text{unlines}_F \ xs)

As one can see, \text{unlines}_F is written in the same applicative style as \text{unlines}. The construction principle is: if the original function handles data that one would like to update bidirectionally (e.g., \text{String} in this case), replace all manipulations (e.g., \text{catLine} and "") of the data with the corresponding bidirectional versions (e.g., \text{lift2 catLine}_L and \text{new} "").

\text{Lens} \text{unlines}_L accepts updates that do not change the original formatting of the view (i.e., the same number of lines and an empty last line). For example, we have \text{put unlines}_L ["a", "b", "c"] "AA\nBB\nCC\n" = ["a", "b", "c", "AA\nBB\nCC\n"] but \text{put unlines}_L ["a", "b", "c"] "AA\nBB\n" = ⊥ and \text{put unlines}_L ["a", "b", "c"] "AA\nBB\nCC\nD" = ⊥.

**Example 4 (unlines defined by foldr).** Another common way to implement \text{unlines} is to use \text{foldr}, as below.

\text{unlines} = \text{foldr} \text{catLine} ""

The same coding principle for constructing bidirectional versions applies.

\text{unlines}_L :: \text{Lens} [\text{String}] \text{String}
\text{unlines}_L = \text{unliftList} \text{unlines}_F
\text{unlines}_F :: \forall s. [\text{L} s \text{ String}] \rightarrow \text{L} s \text{ String}
\text{unlines}_F = \text{foldr} (\text{curry} (\text{lift2 catLine}_L)) (\text{new} "")

The new \text{unlines}_F is again in the same applicative style as the new \text{unlines}, where the unidirectional function \text{foldr} is applied to normal functions and lens functions alike. □

For readers familiar with the literature of bidirectional transformation, this restriction to in-place updates is very similar to that in semantic bidirectionalization (Matsuda & Wang 2013; Voigtländer 2009a; Wang & Najd 2014). We will discuss the connection in Section 9.1.
4.2 Datatype-Generic Unlifting Functions

The treatment of lists is an instance of the general case of container-like datatypes. We can view any container with \( n \) elements as an \( n \)-tuple, only to have list length replaced by the more general container shape. In this section, we define a generic version of our technique that works for many datatypes.

Specifically, we use the datatype-generic function `traverse`, which can be found in `Data.Traversable`, to give data-type generic lifting and unlifting functions.

\[
traverse :: (Traversable t, Applicative f) \Rightarrow (a \rightarrow f b) \rightarrow t a \rightarrow f (t b)
\]

We use `traverse` to define two functions that are able to extract data from the structure holding them (`contents`), and redecorate an “empty” structure with given data (`fill`).

```haskell
newtype Const a b = Const { getConst :: a }

contents :: Traversable t \Rightarrow t a \rightarrow [a]
contents t = getConst (traverse (\x \rightarrow Const [x]) t)

fill :: Traversable t \Rightarrow t b \rightarrow [a] \rightarrow t a
fill t \ell = evalState (traverse next t) \ell
    where next _ = do (a : x) \leftarrow Control.Monad.State.get
                     Control.Monad.State.put x
                     return a
```

Here, `Const a b` is an instance of the Haskell `Functor` that ignores its argument `b`. It becomes an instance of `Applicative` if `a` is an instance of `Monoid`. We qualified the state monad operations `get` and `put` to distinguish them from the `get` and `put` as bidirectional transformations.

For many datatypes such as lists and trees, instances of `Traversable` are straightforward to define to the extent of being systematically derivable (McBride & Paterson 2008). The instances of `Traversable` must satisfy certain laws (Bird et al. 2013); and for such lawful instances, we have

\[
\text{fill} \ (\text{fmap} \ f \ t) \ (\text{contents} \ t) = t \quad \text{(FillContents)}
\]

\[
\text{contents} \ (\text{fill} \ t \ xs) = xs \quad \text{if} \quad \text{length} \ xs = \text{length} \ (\text{contents} \ t) \quad \text{(ContentsFill)}
\]

for any `f` and `t`, which are needed to established the correctness of our generic algorithm. Note that every `Traversable` instance is also an instance of `Functor`.

We can now define a generic `lsequence` function as follows.

\[
lsequence :: (Eq a, Eq (t b)), Traversable t \Rightarrow t (L s a) \rightarrow L s (t a)
lsequence t = \text{lift} \ (\text{fillL} \ (\text{shape} \ t)) \ (\text{lsequenceList} \ (\text{contents} \ t))
    \quad \text{where}
    \text{fillL} \ s = \text{Lens} \ (\lambda xss \rightarrow \text{fill} \ s \ xs) \ (\lambda _t \rightarrow \text{contents}' \ s \ t)
    \text{contents}' \ s \ t = \text{if} \ \text{shape} \ t \ == \ s \ \text{then} \ \text{contents} \ t
                           \text{else} \quad \text{error} \ "\text{Shape Mismatch}"
\]

2 In GHC, the function `contents` is called `toList`, which is defined in `Data.Foldable` (Every `Traversable` instance is also an instance of `Foldable`). We use the name `contents` to emphasize the function’s role of extracting contents from structures (Bird et al. 2013).
Here, \( \text{shape} \) computes the shape of a structure by replacing elements with units, i.e.,
\[
\text{shape } t = \text{fmap } (\lambda \rightarrow ()) t.
\]
Also, we can make a \( \text{Poset} \) instance as follows.

\[
\text{instance } (\text{Poset } a, \text{Eq } (t())), \text{Traversable } t \Rightarrow \text{Poset } (t \ a) \text{ where }
\]
\[
t_1 \triangleright t_2 = \begin{cases} \text{fill } t_1 (\text{contents } t_1 \triangleright \text{contents } t_2) & \text{if } \text{shape } t_1 = \text{shape } t_2 \\ \bot & \text{else} \end{cases}
\]

Following the example of lists, we have a generic unlifting function with \( \text{length} \) replaced by \( \text{shape} \).

\[
\text{unliftT} :: (\text{Eq } (t())), \text{Eq } a, \text{Traversable } t \Rightarrow (\forall s. t (L \ s \ a) \rightarrow L \ s \ b) \rightarrow \text{Lens } (t \ a) b
\]

\[
\text{where}
\]
\[
\text{mkLens } s = f (\text{projTs } (\text{shape } s)) \circ \text{tagT}_L
\]
\[
\text{tagT}_L = \text{Lens } (\text{fmap } O) \circ \text{const } \text{fmap } \text{unTag}
\]
\[
\text{projTs } sh = \text{let } n = \text{length } (\text{contents } sh) \text{ in } \text{fill } sh [\text{projT}_L i \ sh | i \leftarrow [0..n-1]]
\]
\[
\text{projT}_L i \ sh = \text{Lens } (\lambda s \rightarrow \text{unTag } (\text{contents } s!!i))
\]
\[
(\lambda s \ v \rightarrow \text{fill } sh (\text{update } i (U \ v) (\text{contents } s)))
\]

Here, \( \text{projT}_L i \ t \) is a bidirectional transformation that extracts the \( i \)th element in \( t \) with the tag erased. Similarly to \( \text{unlift}_{\text{list}} \), the shape of the source is an invariant of the derived lens.

5 An Application: Bidirectional Evaluation

In this section, we demonstrate the expressiveness of our framework by defining a bidirectional evaluator in it. As we will see in a larger scale, programming in our framework is very similar to what it is in conventional unidirectional languages, showing the distinct advantage of our approach.

An evaluator can be seen as a mapping from an environment to a value of a given expression. A bidirectional evaluator (Hidaka et al. 2010) additionally takes the same expression but maps an updated value of the expression back to an updated environment, so that evaluating the expression under the updated environment results in the value.

Consider the following syntax for a higher-order call-by-value language.

\[
\text{data } \text{Exp} = \text{ENum } \text{Int} | \text{EInc } \text{Exp} \\
| \text{EVar } \text{String} | \text{EApp } \text{Exp} \text{Exp}
\]

\[
\text{data } \text{Val } a = \text{VNum } a \\
| \text{VFun } \text{String} \text{Exp } (\text{Env } a) \text{ deriving } \text{Eq}
\]

\[
\text{data } \text{Env } a = \text{Env } [(\text{String}, \text{Val } a)] \text{ deriving } \text{Eq}
\]

This definition is standard, except that the type of values is parameterized to accommodate both \( \text{Val } (L \ s \ \text{Int}) \) and \( \text{Val } \text{Int} \) for updatable and ordinary integers, and so does the type of environments. It is not difficult to make \( \text{Val} \) and \( \text{Env} \) instances of \( \text{Traversable} \).

\[3\] This definition actually overlaps with those for lists and pairs. So we either need to have “wrapper” type constructors, or enable \texttt{OverlappingInstances}.\]
Using our framework, writing a bidirectional evaluator is almost as easy as writing the usual unidirectional one.

\[
\text{eval} :: \text{Env} (L s \text{ Int}) \rightarrow \text{Exp} \rightarrow \text{Val} (L s \text{ Int})
\]

\[
\text{eval env} (\text{ENum } n) = \text{VNum} (\text{new } n)
\]

\[
\text{eval env} (\text{EInc } e) = \text{let } \text{VNum } v = \text{eval env } e \text{ in } \text{VNum} (\text{lift inc}_L v)
\]

\[
\text{eval env} (\text{EVar } x) = \text{lkup } x \text{ env}
\]

\[
\text{eval env} (\text{EApp } e_1 e_2) = \text{let } \text{VFun } x e' \text{ (Env env')} = \text{eval env } e_1 \text{ in } \text{eval } (\text{Env } ((x, v_2) : \text{env}')) e'
\]

\[
\text{eval env} (\text{EFun } x e) = \text{VFun } x e \text{ env}
\]

Here, \( \text{inc}_L :: \text{Lens } \text{Int } \text{Int} \) is a bidirectional version of \((+1)\) that can be defined as follows.

\[
\text{inc}_L = \text{Lens } (+1) (\lambda x \rightarrow x - 1)
\]

and \( \text{lkup} :: \text{String} \rightarrow \text{Env } a \rightarrow a \) is a lookup function.

A lens \( \text{eval}_L :: \text{Exp} \rightarrow \text{Lens } (\text{Env } \text{Int}) (\text{Val } \text{Int}) \) naturally arises from \( \text{eval} \).

\[
\text{eval}_L e = \text{unliftT } (\lambda \text{env} \rightarrow \text{liftT } \text{idL } \text{eval } e)
\]

As an example, let’s consider the following expression which essentially computes \( x + 65536 \) by using a higher-order function \( \text{twice} \) in the object language.

\[
\text{expr} = \text{twice} \text{ twice} \text{ twice} \text{ twice} \text{ twice} \text{ inc} \text{ x}
\]

\[
\text{where}
\]

\[
\text{twice } = \text{EFun } "f" \text{ } \text{EFun } "x" \text{ } \text{EFun } "f" \text{ } \text{EFun } "x" (\text{EFun } "f" \text{ } \text{EFun } "x")
\]

\[
x = \text{EVar } "x"
\]

\[
\text{inc } = \text{EFun } "x" \text{ } \text{EInc } (\text{EVar } "x")
\]

\[
\text{infixl } 9 \text{ @@ -- @@ is left associative}
\]

\[
(\text{@@}) = \text{EApp}
\]

For easy reading, we translate the above expression to Haskell syntax.

\[
\text{expr} = (((((\text{twice} \text{ twice}) \text{ twice}) \text{ twice}) \text{ inc}) \text{ x}
\]

\[
\text{where}
\]

\[
\text{twice } f \text{ } x = f \text{ (f x)}
\]

\[
\text{inc } x = x + 1
\]

Now giving an environment that binds the free variable \( x \), we can run the bidirectional evaluator as follows, with \( \text{env}_0 = \text{Env } [("x", \text{VNum } 3)] \).

\[
\text{Main} > \text{get } (\text{eval}_L \text{ expr}) \text{ env}_0
\]

\[
\text{VNum } 65539
\]

\[
\text{Main} > \text{put } (\text{eval}_L \text{ expr}) \text{ env}_0 (\text{VNum } 65536)
\]

\[
\text{Env } [("x", \text{VNum } 0)]
\]

As a remark, this seemingly innocent implementation of \( \text{eval}_L \) is actually highly non-trivial. It essentially defines compositional (or modular) bidirectionalization (Matsuda & Wang 2013; Matsuda et al. 2007; Voigtländer 2009a; Wang & Najd 2014) of programs that
are monomorphic in type and use higher-order functions in definition—something that has not been achieved in bidirectional-transformation research so far.

6 Extensions

In this section, we extend our framework in two dimensions: allowing shape changes via lifting lens combinators, and allowing \((L_s A)\)-values to be inspected during forward transformations following our previous work (Matsuda & Wang 2013, 2014).

6.1 Lifting Lens-Combinators

An advantage of the original lens combinators (Foster et al. 2007) (that operate directly on the non-functional representation of lenses) over what we have presented so far is the ability to accept shape changes to views. We argue that our framework is general enough to easily incorporate such lens combinators.

Since we already know how to lift/unlift lenses, it only takes some plumbing to be able to handle lens combinators, which are simply functions over lenses. For example, for combinators of type \(\text{Lens } A B \rightarrow \text{Lens } C D\) we have

\[
\text{liftC} :: \text{Eq } a \Rightarrow (\text{Lens } a b \rightarrow \text{Lens } c d) \rightarrow (\forall s. L s a \rightarrow L s b) \rightarrow (\forall t. L t c \rightarrow L t d)
\]

\[
\text{liftC } c f = \text{lift } (c \circ \text{unlift } f)
\]

Using the analogy to higher-order abstract syntax (Church 1940; Huet & Lang 1978; Miller & Nadathur 1987; Pfenning & Elliott 1988), the polymorphic arguments of the lifted combinators represent closed expressions; for example, a program like \(\lambda x \rightarrow \ldots c \ldots x \ldots \ldots\) does not type-check when \(c\) is a lifted combinator.

As an example, let us consider the following lens combinator \(\text{mapDefault}_C\).

\[
\text{mapDefault}_C :: a \rightarrow \text{Lens } a b \rightarrow \text{Lens } [a] [b]
\]

\[
\text{mapDefault}_C d \ell = \text{Lens } (\text{map } (\text{get } \ell)) (\lambda s v \rightarrow \text{go } s v)
\]

\[
\text{where go } ss [] = []
\]

\[
go [] (v:vs) = \text{put } \ell d v : \text{go } [] vs
\]

\[
go (s:ss) (v:vs) = \text{put } \ell s v : \text{go } ss vs
\]

When given a lens on elements, \(\text{mapDefault}_C d\) turns it into a lens on lists. The default value \(d\) is used when new elements are inserted to the view, making the list lengths different. We can incorporate this behavior into our framework. For example, we can use \(\text{mapDefault}_C\) as in the following, which in the forward direction is essentially \(\text{map } (\text{uncurry } (+))\).

\[
\text{mapAdd}_L :: \text{Lens } [(\text{Int},\text{Int})] [\text{Int}]
\]

\[
\text{mapAdd}_L = \text{unlift } \text{mapAdd}_F
\]

\[
\text{mapAdd}_F :: \forall t. L t [(\text{Int},\text{Int})] \rightarrow L t [\text{Int}]
\]

\[
\text{mapAdd}_F xs = \text{mapF } (0,0) (\text{lift } \text{addL}) xs
\]

\[
\text{mapF} :: \text{Eq } a \Rightarrow a \rightarrow (\forall s. L s a \rightarrow L s b) \rightarrow (\forall t. L t [a] \rightarrow L t [b])
\]

\[
\text{mapF } d = \text{liftC } (\text{mapDefault}_C d)
\]

\[
\text{addL} :: \text{Lens } (\text{Int},\text{Int}) \text{ Int}
\]

\[
\text{addL} = \text{Lens } (\lambda (x,y) \rightarrow x + y) (\lambda (x,\_ ) v \rightarrow (x,v-x))
\]
This lens $mapAdd_L$ constructed in our framework handles shape changes without any trouble.

Main> put $mapAdd_L$ [(1,1),(2,2)] [3,5]
[(1,2),(2,3)]
Main> put $mapAdd_L$ [(1,1),(2,2)] [3]
[(1,2)]
Main> put $mapAdd_L$ [(1,1),(2,2)] [3,5,7]
[(1,2),(2,3),(0,7)]

The trick is that the expression $map_F (0,0) (lift addL)$ has type $\forall s. L s [[Int,Int]] \rightarrow L s [Int]$, where the list occurs inside $L s$, contrasting to $map (lift addL)$’s type $\forall s. [L s (Int,Int)] \rightarrow [L s Int]$. Intuitively, the type constructor $L s$ can be seen as an updatability annotation; $L s [[Int,Int]]$ means that the list itself is updatable, whereas $[L s (Int,Int)]$ means that only the elements are updatable. Here is the trade-off: the former has better updatability at the cost of a special lifted lens combinator; the latter has less updatability but simply uses the usual $map$ directly. Our framework enables programmers to choose either style, or anywhere in between freely.

This position-based approach used in $mapDefault_C$ is not the only way to resolve shape discrepancies. We can also match elements according to keys (Barbosa et al. 2010; Foster et al. 2010). As an example, let us consider a variant of the map combinator.

$mapByKey_C :: Eq k \rightarrow a \rightarrow Lens a b \rightarrow Lens [(k,a)] [(k,b)]$

$mapByKey_C d \ell = Lens (map (\lambda (k,s) \rightarrow (k, get \ell s))) (\lambda s v \rightarrow go s v)$

where $go ss [] = []$

$go ss (k,v) : vs = case lookup k ss of$

Nothing $\rightarrow (k,put \ell d v) : go ss vs$

Just $s \rightarrow (k,put \ell s v) : go (del k ss) vs$

$del k [] = []$

$del k (k',s) : ss | k = k' = ss$

otherwise $= (k',s) : del k ss$

Lenses constructed with $mapByKey_C$ match with keys instead of positions.

$mapAddByKeyYL :: Eq k \Rightarrow Lens [(k, (Int,Int))] [(k, Int)]$

$mapAddByKeyYL = unlift mapAddByKeyF$

$mapAddByKeyYF :: Eq k \Rightarrow \forall s. L s [(k, (Int,Int))] \rightarrow L s [(k, Int)]$

$mapAddByKeyYF xs = mapByKeyYF (0,0) (lift addL) xs$

$mapByKeyYF :: (Eq k, Eq a) \Rightarrow$

$\forall s. L s a \rightarrow L s b \rightarrow (\forall s. L t [(k,a)] \rightarrow L t [(k,b)])$

$mapByKeyYF d = liftC (mapByKeyC d)$

Let $s$ be ["A",(1,1)], ["B",(2,2)]. Then, the obtained lens works as follows.

Main> put $mapAddByKeyYL$ s ["B",5],["A",3]
["B",(2,3)],["A",(1,2)]
Main> put $mapAddByKeyYL$ s ["A",3]
["A",(1,2)]
6.2 Observations of Lifted Values

So far we have programmed bidirectional transformations ranging from polymorphic to monomorphic functions. For example, \texttt{unlines} is monomorphic because its base case returns a String constant, which is nicely handled in our framework by the function \texttt{new}. At the same time, it is also obvious that the creation of constant values is not the only cause of a transformation being monomorphic (Matsuda & Wang 2013, 2014). For example, let us consider the following toy program.

\[\text{bad} (x, y) = \begin{cases} \text{if } x \neq \text{new } 0 \text{ then } (x, y) \text{ else } (x, \text{new } 1) \end{cases}\]

In this program, the behavior of the transformation depends on the “observation” made to a value that may potentially be updated in the view. Then the naively obtained lens

\[\text{bad} \calL = \text{unlift}_2 (\text{lift}_2 \text{id} \circ \text{bad})\]

would violate well-behavedness, as \[\text{put bad} \calL (0, 2) (1, 2) = (1, 2)\] but \[\text{get bad} \calL (1, 2) = (1, 1)\].

Our previous work (Matsuda & Wang 2013, 2014) tackles this problem by using a monad to record observations, and to enforce that the recorded observation results remain unchanged while executing \texttt{put}. The same technique can be used in our framework, and actually in a simpler way due to our new compositional formalization.

\[\text{newtype } R a b = \text{R} (\text{Poset } a \Rightarrow a \rightarrow (b, a \rightarrow \text{Bool}))\]

We can see that \(R A B\) represents \texttt{get}s with restricted source updates: taking a source \(s :: A\), it returns a view of type \(B\) together with a constraint of type \(A \rightarrow \text{Bool}\) which must remain satisfied amid updates of \(s\). Formally, giving \(R m :: R A B\), for any \(s\), if \((s, p) = m s\) then we have: (1) \(p s = \text{True}\); (2) \(p s' = \text{True}\) implies \(m s = m s'\) for any \(s'\). It is not difficult to make \(R s\) an instance of \texttt{Monad}—it is a composition of \texttt{Reader} and \texttt{Writer} monads. We only show the definition of \((\Rightarrow\Rightarrow)\).

\[R m \Rightarrow\Rightarrow f = R \# \lambda s \rightarrow \text{let } (x, c_1) = m s (y, c_2) = \text{let } k = f x \text{ in } k s \text{ in } (y, (\lambda s \rightarrow c_1 s \land c_2 s) s)\]

Then, we define a function that produces \(R\) values, and a version of unlifting that enforces the observations gathered.

\[\text{observe} :: \text{Eq } w \Rightarrow \text{L } s \text{ w } \Rightarrow \text{R } s \text{ w}\]

\[\text{observe } x = R \lambda s \rightarrow \text{let } w = \text{get } x \text{ s } \text{ in } (w, (\lambda s' \rightarrow \text{get } x s' \Rightarrow w))\]

\[\text{unliftM}_2 :: (\text{Eq } a, \text{Eq } b) \Rightarrow (\forall s. (\text{L } s \text{ a}, \text{L } s \text{ b}) \Rightarrow \text{R } s \text{ (L } c \text{)) } \Rightarrow \text{Lens } (a, b) c\]

\[\text{unliftM}_2 f = \text{Lens } (\lambda s \rightarrow \text{get } (\text{mkLens } f s) s) (\lambda s \rightarrow \text{put } (\text{mkLens } f s) s)\]

\[\text{where}\]

\[\text{This code actually does not type check as } (\Rightarrow\Rightarrow) \text{ on } (L s \text{ Int})\text{-values depends on a source and has to be implemented monadically. But we do not fix this program as it is meant to be a non-solution that will be discarded.}\]
We postpone the proof till Section 8.

well-behavedness is guaranteed as long as liftO and liftM are abstract. Then

Let Definition 4 (Abstract Nature of L and R). We say L and R are abstract in \( f :: \tau \) if there is a polymorphic function \( h \) of type

\[
\forall \ell. (\forall a b. Lens a b \to (\forall s. \ell s a \to \ell s b))
\to (\forall a b. (\forall s. \ell s a \to \ell s b) \to Lens a b)
\to (\forall s. \ell s ())
\to (\forall a b. \ell s a \to \ell s b \to \ell s (a,b))
\to (\forall a b c. (\forall s. (\ell s a, \ell s b) \to \ell s c) \to Lens (a,b) c)
\to (\forall s w. Eq w \Rightarrow \ell s w \Rightarrow r s w)
\to (\forall a b. (\forall s. \ell s a \to r s (\ell s b)) \to Lens a b)
\to (\forall a b c. (\forall s. (\ell s a, \ell s b) \to r s (\ell s c)) \to Lens (a,b) c)
\to \tau'
\]

satisfying \( f = h \) lift unlift unit (\( \oplus \)) unlift2 observe unliftM unliftM2 and \( \tau' = \tau[\ell/L, r/R] \).

Note that, similarly to unliftM2, we can define unliftM and unliftMT, as monadic versions of unlift and unliftT. Formally, we have the following theorem.

Theorem 6. Let \( f \) be a function of type \( \forall s. (L s A, L s B) \to R s (L s C) \) in which L and R are abstract. Then unliftM2 f is well-behaved, if all the following conditions hold.

- only well-behaved lenses are passed to lift during evaluation,
- \( w \) in observe :: \( Eq w \Rightarrow L s w \Rightarrow R s w \) is only instantiated to types \( W \) such that \( (\oplus) \) on \( W \) coincides with the semantic (observational) equality.

We postpone the proof till Section 8.

We can now place observe at where observations happens, and use unliftM to guard against changes to them.

\[
good :: \forall s. (L s Int, L s Int) \to R s (L s (Int, Int))
good (x, y) = \text{do } b \leftarrow \text{liftO2 } (\oplus) x (\text{new } 0)
\text{return } (\text{if } b \text{ then } x \oplus y \text{ else } x \oplus \text{new } 1)
\]

Here, liftO2 is defined as follows.

\[
\text{liftO2 :: } Eq \Rightarrow (a \to b \to w) \to L s a \to L s b \to R s w
\text{liftO2 } p x y = \text{liftO } (\text{uncurry } p) (x \oplus y)
\text{liftO :: } Eq \Rightarrow (a \to w) \to L s a \to R s w
\]

Applicative Bidirectional Programming
lifto p x = observe (lift (Lens p unused) x)

where unused s v | v = p s = s

Then the obtained lens goodL = unliftM2 good successfully rejects illegal updates, as

\[ \text{put goodL (0, 2) (1, 2) = } \perp \]

Note that unused is unused as it stands in our framework; recall that observe x only uses the get component of x.

One might have noticed that the definition of good is in the Monadic style—not applicative in the sense of (McBride & Paterson 2008). This is necessary for handling observations, as the effect of \((R s)\) can depend on the value in it (Lindley et al. 2011).

Example 5 \((\text{nub})\). As a slightly involved example, let us consider a bidirectional version of nub, which removes duplicate elements in a list as 

\[ \text{nub} [1, 1, 2, 3, 2] = [1, 2, 3]. \]

\[
\begin{align*}
nubF &:: \text{Eq a} \Rightarrow [L s a] \rightarrow R s [L s a] \\
nubF [] & = \text{return []} \\
nubF (x:xs) & = \text{do xs' ← deleteF x xs} \\
 & \quad \text{return (x:rs')} \\
deleteF &:: \text{Eq a} \Rightarrow L s a \rightarrow [L s a] \rightarrow R s [L s a] \\
deleteF [] & = \text{return []} \\
deleteF (y:ys) & = \text{do b ← lifto2 (zz) x y} \\
 & \quad r ← deleteF x ys \\
 & \quad \text{return (if b then r else y:r)} \\
nubL &:: \text{Eq a} \Rightarrow \text{Lens} [a] [a] \\
nubL = \text{unliftMT (fmap lsequence ◦ nubF)}
\end{align*}
\]

The obtained lens nubL works as follows.

Main> get nubL [1, 1, 2, 3, 2] 
[1,2,3]
Main> put nubL [1, 1, 2, 3, 2] [1, 2, 6] 
[1,1,2,6,2]

However, there is a limitation: nubL cannot change any duplicated elements.

Main> put nubL [1, 1, 2, 3, 2] [1, 5, 6] 
*** Exception: Changed Observation

Unlike the previous example that updates 3, we have two copies of 2 in the source: the first one appears as the third element and the second one appears as the last element. They are compared by zz, and the first one comes in the view while the second one is dropped. This also imposes a constraint on the source that the third element and the last element must be equal (but not necessarily remain as 2). Thus, we cannot change the 2 in the view because it changes only the first occurrence of 2 while leaving the second occurrence untouched.

Voigtlander (2009a) addresses the problem by treating equal elements in the source as the “same”, where a change to one automatically triggers a change to others. In the above example, if we can update both occurrences of 2 simultaneously to 5, no bidirectional laws will be violated.
With a small amount of additional work, we can incorporate this idea while keeping the definition of \( nubF \). First, we prepare a datatype in which the “same” elements are merged to one.

\[ \text{data} \ EList \ a = \ EList \ [\ \text{Int}] \ [(\text{Int}, a)] \]

Intuitively, \( EList \) indexes elements: its first parameter is the list of \( \text{Int} \)-indices and the second parameter is an injective mapping from the indices to actual list elements. It is easy to decompose a list to \( EList \), and vice versa.

\[
\text{decompose} :: \text{Eq} \ a \Rightarrow [a] \rightarrow EList \ a \\
\text{decompose} \ xs = \text{let} \ ys = \text{nub} \ xs \in EList \ \text{fromJust} \ (\text{findIndex} \ (\_ \mapsto x) \ ys) \mid x \leftarrow xs \ (\text{zip} \ [0..] \ ys) \\
\text{recompose} :: EList \ a \rightarrow [a] \\
\text{recompose} \ (EList \ is \ m) = [\text{fromJust} \ (\text{lookup} \ i \ m) \mid i \leftarrow is]
\]

Here, \( \text{findIndex} :: \text{Eq} \ a \Rightarrow a \rightarrow [a] \rightarrow \text{Maybe} \ \text{Int} \) defined in \text{Data.List}, is a function that takes an element \( x \) and a list \( xs \), and returns the index of the first occurrence of \( x \) in \( xs \) if it exists. The function \( \text{fromJust} \) is a function defined by \( \text{fromJust} \ (\text{Just} \ x) = x \). For example, \( \text{decompose} \ [A, A, B, C, B] \) results in \( EList \ [0, 0, 1, 2, 1] \ [(0, A), (1, B), (2, C)] \).

From the two functions \( \text{decompose} \) and \( \text{recompose} \), we can define lens \( \text{decomposeL} \) as follows.

\[
\text{decomposeL} :: \text{Eq} \ a \Rightarrow \text{Lens} \ [a] \ (EList \ a) \\
\text{decomposeL} = \text{Lens} \ \text{decompose} \ (\lambda \_ \ v \mapsto \text{recompose}' \ v) \\
\text{where} \ \text{recompose}' \ v = \text{let} \ s = \text{recompose} \ v \in \text{if} \ v \neq \text{decompose} \ s \text{ then } s \text{ else } \bot
\]

Function \( \text{recompose}' \) is a variant of \( \text{recompose} \) that actually checks the invariant on \( EList \). That is, for \( EList \ is \ m \), \( m \) must be injective and defined for all the indices in \( is \). This check is conservative, but works fine for our purpose.

Now, we are ready to generalize \( \text{nubL} \).

\[
\text{nubL}' :: \text{Eq} \ a \Rightarrow \text{Lens} \ [a] \ [a] \\
\text{nubL}' = \text{unliftMT} \ (\lambda \_ \ xs \rightarrow \text{fmap} \ \text{sequence} \ (\text{nub} \ (\text{recompose} \ xs))) \circ \text{decomposeL}
\]

Note that \( \text{recompose} \ xs \) type-checks because \( \text{recompose} :: EList \ a \rightarrow [a] \) does not require \( \text{Eq} \) for \( a \).

The new lens \( \text{nubL}' \) accepts more updates than \( \text{nubL} \).

\[
\text{Main> put nubL'} \ [1, 1, 2, 3, 2] \ [4, 5, 6] \\
[4, 4, 5, 6, 5]
\]

without compromising the bidirectional laws.

\[
\text{Main> put nubL'} \ [1, 1, 2, 3, 2] \ [4, 5, 5] \\
*** \text{Exception: Changed Observation}
\]

As a remark, automatically treating all equal elements as the same may not always be the most desirable. Our previous work (Matsuda & Wang 2014) addresses the problem by selective indexing: only the elements that pass an equality check occurring in the execution...
of get are considered the same. It is not obvious how our current framework can be extended to achieve this because now elements can be compared after applying lifted lens functions, which may require us to index elements in intermediate views, unlike the situation in previous work (Matsuda & Wang 2014; Voigtlander 2009a) where only source elements are indexed.

7 An XML Transformation Example

XML transformation is a common application area of bidirectional programming, where data in different XML formats are synchronized through transformations going both ways. In this section, we program such transformations in our framework with the extensions discussed in Section 6.2. Specifically, we implement a slightly simplified version of the query Q5 of Use Case “STRING” in XML Query Use Cases (http://www.w3.org/TR/xquery-use-cases). Different from the existing first-order languages specialized for bidirectional XML transformations (Fegaras 2010; Liu et al. 2007; Pacheco et al. 2014a), our language is general purpose, and, as will be demonstrated by this exercise, can be seamlessly integrated with an existing functional framework for transforming XML that involves higher-order features.

The basic idea follows from our previous work (Matsuda & Wang 2013, 2014). We use the established HaXML framework (Wallace & Runciman 1999) to construct XML transformations using filters—functions of type \(a \rightarrow [b]\). Adapting it to our context of bidirectional transformations with observations, we will use filters of type \(L s a \rightarrow ListT (R s) (L s b)\), where the monad transformer \(ListT\) in Control.Monad.List is defined by

\[
\text{newtype ListT m a = ListT} \{ \text{runListT :: m [a]} \}
\]

with an implementation of the function “lift” of type \(\text{Monad m} \Rightarrow m a \rightarrow \text{ListT m a}\). To avoid name conflicts, we use the following type-specialized version.

\[
\text{liftListT :: Monad m} \Rightarrow m a \rightarrow \text{ListT m a}
\]

\[
\text{liftListT = Control.Monad.Trans.lift}
\]

The type constructor \(ListT m\) is an instance of \(\text{MonadPlus}\) in \(\text{Control.Monad}\), which gives us \(\text{mplus :: MonadPlus m} \Rightarrow m a \rightarrow m a \rightarrow m a\) and \(\text{mzero :: MonadPlus m} \Rightarrow m a\). For those who are familiar with monad transformer laws, \(R s\) is a commutative monad in our case, and thus \(ListT (R s)\) is a monad.

7.1 A Datatype for XML

To start with, we define a datatype to represent XML elements. Following our previous work (Matsuda & Wang 2013, 2014), we use a simple rose-tree representation as follows.

\[
\text{data Tree a = Node a [Tree a] deriving (Eq, Functor, Foldable, Traversable)}
\]

\[
\text{data Label = E String | T String deriving Eq}
\]

Here, \(E\) and \(T\) stand for “element name” and “text” respectively. We shall omit other features of XML that cannot be expressed in this datatype, notably attributes, IDs and IDREFs, schemas, and namespaces.
For example, an XML fragment

```
<content><par>Today, Gorilla Corporation announced that ...</par>
<par>As a result of this acquisition, ...</par></content>
```

is represented as follows.

\[
\text{Node (E "content") [}
\text{Node (E "par") [}
\text{Node (T "Today, Gorilla Corporation announced that ...") [],}
\text{Node (E "par") [}
\text{Node (T "As a result of this acquisition, ...") []]}
\text{]}]
\]

The following function \textit{label} is sometimes useful to write examples.

\[
\text{label} :: \text{Tree } a \rightarrow a
\]

\[
\text{label (Node lab _)} = \text{lab}
\]

Then, we define a type of (bidirectional) filters as follows.

\[
\text{type } B\text{Filter } s a = \text{Tree (L } s a \rightarrow \text{ListT (R } s \rightarrow \text{Tree (L } s a))}
\]

### 7.2 Basic Filters

As in our previous work (Matsuda & Wang 2013, 2014), we introduce several basic filters.

The simplest filter \textit{keep} keeps its input.

\[
\text{keep} :: B\text{Filter } s a
\]

\[
\text{keep } x = \text{return } x
\]

Filter \textit{children} extracts the children of a node.

\[
\text{children} :: B\text{Filter } s a
\]

\[
\text{children (Node } _ ts) = \text{ListT } $ \text{return } ts
\]

Filter \textit{ofLabel} \textit{lab} returns the input if its root has the label \textit{lab}, and fails otherwise.

\[
\text{ofLabel} :: L s \text{ Label } \rightarrow B\text{Filter } s \text{ Label}
\]

\[
\text{ofLabel } \text{lab } t = \text{do } \text{guardM } $ \text{liftListT } $ \text{liftO}_2 \ (\Rightarrow) \ (\text{lab } t) \ \text{lab}
\]

\[
\text{return } t
\]

Here, \textit{guardM} is a variant of \textit{guard} from \textbf{Control.Monad} which takes a monadic argument instead (function \textit{guard} fails if its argument is \textit{False}, and does nothing otherwise.)

\[
\text{guardM} :: \text{MonadPlus } m \Rightarrow m \text{ Bool } \rightarrow m ()
\]

\[
\text{guardM } x = x \Rightarrow \text{guard}
\]

Filters are composable by combinators.

\[
(/>): B\text{Filter } s a \rightarrow B\text{Filter } s a \rightarrow B\text{Filter } s a
\]

\[
f /> g = f \Rightarrow \text{children} \Rightarrow g
\]

Here, \(\Rightarrow\) is the Kleisli composition operator in \textbf{Control.Monad} defined by \((f \Rightarrow g) x = f x \Rightarrow g\). The operator \((/>\) is useful for implementing the XPath axis "\(//\)". For example, the
Kazutaka Matsuda and Meng Wang

filter keep /> ofLabel (new (E "content")) extracts content elements from the children of its input, and the filter keep /> keep /> keep extracts the grandchildren of its input.

Another useful combinator is deep defined as follows.

```
dep s a → BFilter s a
deep f t = bfs (t []]
where
  bfs [] = mzero
  bfs [] qs = bfs (reverse qs) []
  bfs (t@ (Node lab ts) :rest) qs = do
    ck ← gather f t
    case ck of
      [] → bfs rest (reverse ts ++ qs)
      _ → return t‘mplus‘bfs rest qs
```

The expression deep f t applies filter f to each subtree of t in the breadth-first manner, and combines by mplus the subtrees for which f succeeds. An auxiliary function gather gathers results: for example children y produces one child at a time, and gather (children y) gathers the children in a list.

```
gather :: Monad m ⇒ ListT m a → ListT m [a]
gather (ListT x) = ListT (λa → return [a])
```

Combinator deep is useful for implementing the XPath axis “//”. For example, the filter deep (ofLabel (new $ E "news_item")) returns all the news_item elements within the input tree.

Sometimes, we want to extract the nth element of a query result. This is done by using the filter /!n defined as follows.

```
(/!n) :: BFilter s a → Int → BFilter s a
f /! n = λxs → do
  rs ← gather f xs
  return (rs !! n)
```

7.3 Query Example

Now, we are ready to write a bidirectional query of Q5 (of Use Case “STRING” in XML Query Use Cases). The query extracts summaries of the news items (specifically, titles, dates and the first paragraphs) that contains “Gorilla Corporation” in their “content”s; for example, for the input shown in Figure 1, it returns the XML shown in Figure 2. Assuming that the input is in a file named “string.xml”, this query is written in XQuery as shown in Figure 3.

Figure 4 shows the bidirectional version of Q5 implemented in our framework. Here, catDateL is a lens whose get takes a triple (t,d,p) and returns a concatenated string with

---

5 Both XMLs are a simplified version of the sample input and output for Q5 of Use Case “STRING” in XML Query Use Cases (http://www.w3.org/TR/xquery-use-cases). In the original, par may contain a sequence of text and elements rather than merely text. This simplification does not affect the original Q5 in XQuery, but does simplify our version written in Haskell.
Applicative Bidirectional Programming

      { string(({$item//par}[1])) } 
    </item_summary>

Fig. 3. Query Q5 of Use Case “String” in XML Query Use Cases

". ", and whose put takes a string in the format "\d\d\d\d-\d\d-\d\d\d\d\d\d\d\d\d\d\" (the Perl-compatible regular-expression format), and decompose it to a triple. The code looks complicated, but this complication mainly comes from writing XML queries in a functional programming language, instead of bidirectional programming. It is worth mentioning that q5 cannot be written in our previous framework (Matsuda & Wang 2013, 2014) as we are
reusing lenses (such as `catDateL`) as blackboxes through lifting—a key advantage of our framework.

### 7.4 Updatability

By applying `get q5L` to the XML data in Figure 1 (encoded in Haskell), we obtain a piece of data that corresponds to the XML in Figure 2. We can update the extracted strings as long as they still contain delimiters matching the regular expression "\d\d\d\d-\d\d-\d\d\d\d. This means other updates such as insertions, deletions and changes to element names `item_summary` are (rightfully) prohibited.

As an example, consider changing the text of the second extracted item as follows.

```
Foobar Corporation is suing Gorilla Corporation today. 2015-10-20.
In surprising developments today, YEAH! ...
```

We have appended "today" to the title part, changed the date string, and inserted "YEAH!". Executing `put q5L` on the new text succeeds and changes the corresponding parts in the original input XML. That is, "today" is appended to the title text, "2015-10-20" is set as the new date and "YEAH!" is inserted in the first paragraph of the content.
8 Correctness

In this section, we prove Theorem 6 (Proofs of Theorems 1 and 4 are similar and thus omitted). Our proof is based on the free theorems (Reynolds 1983; Voigtlander 2009b; Wadler 1989). It is worth noting that we only need to use unary parametricity instead of the binary one adopted in previous approaches (Matsuda & Wang 2013, 2014; Voigtlander 2009a).

8.1 Free Theorem

We firstly review the free theorems based on unary parametricity.

Roughly speaking, free theorems are theorems obtained as corollaries of relational parametricity (Bernardy et al. 2012; Reynolds 1983; Vytiniotis & Weirich 2010), which states that, for a closed term $f$ of type $T$, $f$ belongs to a certain relational interpretation of $T$. A simple example of a free theorem is that a (total) function $f$ of type $\forall \alpha. \alpha \rightarrow \alpha$ is the identity function, because $f$ preserves any properties on the input.

We start by introducing some notations. We write $R :: \text{Pred}(A)$ if $R$ is a unary relation (i.e., a predicate) on $A$; we identified a predicate on $A$ with the set of $A$-elements satisfying the predicate. For predicates $R :: \text{Pred}(A)$ and $R' :: \text{Pred}(B)$, we write $R \rightarrow R' :: \text{Pred}(A \rightarrow B)$ for the predicate on functions $\{ f \mid \forall x \in R, x \in R' \}$, and $(R, R') :: \text{Pred}(A, B)$ for the predicate on pairs $\{(x, y) \mid x \in R, y \in R'\}$. For a polymorphic term $f$ of type $\forall \alpha. T$ and a type $S$, we write $f_S$ for the instantiation of $f$ with $S$, which has type $T[S/\alpha]$. For simplicity, we sometimes omit the subscript and simply write $f$ for $f_S$ if $S$ is clear from the context or irrelevant.

We introduce a unary relational interpretation $[\tau]^1_{\rho}$ of types, where $\rho$ is a mapping from type variables to predicates, as follows.

\[
\begin{align*}
[a]^1_{\rho} & = \rho(\alpha) \\
[B]^1_{\rho} & = \{ e \mid e :: B \} \text{ if } B \text{ is a base type} \\
[T_1 \rightarrow T_2]^1_{\rho} & = [T_1]^1_{\rho} \rightarrow [T_2]^1_{\rho} \\
[\forall \alpha. T]^1_{\rho} & = \left\{ u \mid \forall R :: \text{Pred}(S). u_S \in [T]^1_{\rho[a \rightarrow \forall R]} \right\}.
\end{align*}
\]

Here, $\rho[a \rightarrow \forall R]$ extends $\rho$ with $a \rightarrow \forall R$. If $\rho = \emptyset$, we sometimes write $[T]^1_{\emptyset}$ instead of $[T]^1_{\rho}$.

We abuse the notation to write $[\forall \alpha. \tau]^1_{\rho}$ as $\forall \alpha, \mathcal{F}$ where $\mathcal{F}$ is the interpretation $[[\tau]^1_{\rho[a \rightarrow \forall \alpha. \tau]}]$. For example, we write $\forall R, \forall S : R \rightarrow S$ for $[\forall \alpha, \forall \beta. \mathcal{A} \rightarrow \beta]$. For a base type $B$, we also write $B$ for $[B]^1_{\emptyset}$. We identify the lens type $\text{Lens } A B$ with the pairs of functions $(A \rightarrow B, A \rightarrow B \rightarrow A)$. Accordingly, we write $\text{Lens } S \mathcal{F}$ to mean $(S \rightarrow \mathcal{S}, S \rightarrow \mathcal{S} \rightarrow \mathcal{S})$.

Then, parametricity states that, for a closed term $f$ of a closed type $\tau$, $f$ is in $[\tau]^1_{\emptyset}$. Free theorems are theorems obtained by instantiating parametricity.

Voigtlander (2009b) extends parametricity to a type system with type constructors. A key notion in his result is relational action.

**Definition 5 ((Unary) Relational Action).** For a type constructor $\kappa$, $\mathcal{F}$ is called a relational action on $\kappa$, denoted by $\mathcal{F} :: \text{Pred}(\kappa)$, if $\mathcal{F}$ maps any predicate $R :: \text{Pred}(\tau)$ for every closed type $\tau$ to $\mathcal{F}R :: \text{Pred}(\kappa \tau)$. □
Accordingly, the relational interpretations are extended as:

$$
\begin{align*}
\llbracket \kappa \rrbracket_p^1 &= \rho(\kappa) \\
\llbracket \tau_1 \tau_2 \rrbracket_p^1 &= \llbracket \tau_1 \rrbracket_p^1 \llbracket \tau_2 \rrbracket_p^1 \\
\llbracket \forall \kappa. \tau \rrbracket^1 &= \left\{ u \mid \forall F :: \text{Pred}(\kappa). u_\kappa \in \llbracket \tau \rrbracket_p^{\kappa \rightarrow \tau} \right\}
\end{align*}
$$

Parametricity holds also with this relational interpretation (Bernardy et al. 2012; Vytiniotis & Weirich 2010). Here, $\kappa$ is a type constructor of kind $\star \rightarrow \star$, and thus the quantified $F$ is a relational action. The notation of relational action can be extended to type constructors of kinds $\star \rightarrow \star \rightarrow \star$, $\star \rightarrow \star \rightarrow \star \rightarrow \star$ and so on.

### 8.2 Proof of Theorem 6

First, we state a free theorem for functions of the type mentioned in Definition 4.

**Lemma 3 (A Free Theorem).** Let $f :: \tau$ be a function in which $L$ and $R$ are abstract, and $\tau'$ be a type $\tau'[(L, r) / F]$. For any $F :: \text{Pred}(L)$ and $M :: \text{Pred}(R)$ satisfying the following conditions:

- $\text{lift} \in \forall \forall. \text{Lens } F S T \rightarrow (\forall S. F S T \rightarrow F S T)$.
- $\text{unlift} \in \forall \forall. (\forall S. F S T \rightarrow F S T) \rightarrow \text{Lens } F S T$.
- $\text{unit} \in \forall \forall. \text{Lens } F T (\tau)$.
- $(\ast) \in \forall \forall. (\forall S. F S T \rightarrow F S U) \rightarrow F S (T, U)$.
- $\text{unlift}_2 \in \forall \forall. (\forall S. (F S T, F S U) \rightarrow F S R) \rightarrow \text{Lens } (T, U) R$.
- $\text{observe} \in \forall S. F S T \rightarrow M S T$ for any unary relation $T$ on a type with decidable semantic equality $(\ast\ast)$.
- $\text{unlift}_M \in \forall \forall. (\forall S. F S T \rightarrow M S (F S U)) \rightarrow \text{Lens } (T, U) R$.
- $\text{unliftM}_2 \in \forall \forall. (\forall S. (F S T, F S U) \rightarrow M S (F S R)) \rightarrow \text{Lens } (T, U) R$.

we have $f \in \llbracket \tau \rrbracket_{(L, r) / F, m}$. □

Thanks to the abstract nature of $L$ and $R$ in $f$, we can use Lemma 3. Concretely, we use the following $\mathcal{F}$ and $\mathcal{M}$.

$$
\mathcal{F} S R = \left\{ \ell \mid \ell \in L S R, \ell \text{ is locally well-behaved} \right\}
$$

$$
\mathcal{M} S R = \left\{ \begin{array}{ll}
R m & \forall s \in S. \text{let } (x, p) = m s, \\
x \in R & x \in R \land \ p s = \text{True} \\
\forall s' \in S. p s' = \text{True} \Rightarrow m s = m s' 
\end{array} \right\}
$$

It is worth noting that $\mathcal{F} S R \subseteq L S R$ and $\mathcal{M} S R \subseteq R S R$.

Assume that all the conditions required by Lemma 3 are fulfilled. Then, for a function $f$ of type $\forall s. (L s A, L s B) \rightarrow R s (L s C)$ in which $L$ and $R$ are abstract, we have $f \in (\mathcal{F} S A, \mathcal{F} S B) \rightarrow \mathcal{M} S (\mathcal{F} S C)$ for any predicate $S$. Since $\text{fst}_1$ belongs to $\mathcal{F} (\text{Tag } A, \text{Tag } B) A$ and $\text{snd}_1$ belongs to $\mathcal{F} (\text{Tag } A, \text{Tag } B) B$, we have that $\ell$ in the definition of $\text{mkLens } f s$ called by $\text{unlift}_M f$ is locally well-behaved for all $s$, and thus $\ell'$ is well-behaved by Lemma 2. Since $p (\text{get tag}_2 L s) \triangleright\triangleright \text{True}$ holds from the definition of $M$, $\text{mkLens } f s$ satisfies acceptability. Since $\text{put } (\text{mkLens } f s)$ is less defined than $\text{put } \ell$, $\text{mkLens } f s$ satisfies consistency. This means that $\text{mkLens } f s$ is well-behaved for any $s$. We are left to show $\text{unliftM}_2 f$ is
well-behaved. Although the acceptability of \( \text{unliftM}_2 f \) comes almost directly from the acceptability of \( \text{mkLens} f s \), more effort is needed to show the consistency of \( \text{unliftM}_2 f \). Notice that this is the main difference between Theorem 6 and Theorem 4 after application of the free theorem.

Here, the last line of \( M \) plays an important role. Assume that \( \text{put} (\text{mkLens} f s) s v \) succeeds in \( s' \). We have \( p (\text{get tag2}_L s) = p (\text{get tag2}_L s') = \text{True} \) for \( p \) in the definition of \( \text{mkLens} f s \). Then, by the definition of \( M \), we have that \( (\text{let } R \leftarrow f (\text{fst}_L, \text{snd}_L) \text{ in } (\text{get tag2}_L s)) \) is equal to \( (\text{let } R \leftarrow f (\text{fst}_L', \text{snd}_L') \text{ in } (\text{get tag2}_L s')) \) by \( f (\text{fst}_L', \text{snd}_L') \in M S (S \circ C) \). The rest of computation of \( \text{mkLens} f s \) does not depend on \( s \), and thus \( \text{mkLens} f s = \text{mkLens} f s' \) holds. Therefore, we have

\[
\begin{align*}
\text{get} (\text{unliftM}_2 f) (\text{put} (\text{unliftM}_2 f) s v) \\
\quad = \{ \text{put} (\text{mkLens} f s) s v \text{ succeeds in } s' \} \\
\quad = \{ \text{the above discussion} \} \\
\quad = \{ \text{the consistency of } \text{mkLens} f s \}
\end{align*}
\]

which proves the consistency of \( \text{unliftM}_2 f \).

Now, we go back to show that the conditions in Lemma 3 are actually fulfilled for \( F \) and \( M \).

For the cases of \( \text{lift} \) and \((\otimes)\), we just use Lemma 2. Here, we have used the assumption that \( \text{lift} \) is applied only to well-behaved lenses.

For the case of \( \text{unit} \), the proof is obvious.

For the cases of \( \text{unlift} \), \( \text{unlift}_2 \), \( \text{unliftM} \) and \( \text{unliftM}_2 \), the proofs are straightforward because \( F S R \) is a subset of \( \text{Lens} S R \).

For the case of \( \text{observe} \), the proof is still straightforward. The last two lines of \( M \) are obtained from the fact that \( (\equiv) \) is semantic equality. \( \square \)

Note that, to prove correctness also for the datatype-generic unlifting functions like \( \text{unliftT} \) and \( \text{unliftMT} \), we need to keep an additional invariant that a lens \( t \) in \( F S R \) must be shape-preserving if \( S \) of \( S :: \text{Pred}(S) \) has a shape (recall that \( \text{get} \) and \( \text{put} \) are defined separately also for these datatype-generic functions, and thus similar discussions to \( \text{unliftM} \) are required for them). The above proof still works for this case.

### 9 Related Work and Discussions

In this section, we discuss related techniques to our paper, making connections to a couple of notable bidirectional programming approaches, namely semantic bidirectionalization and the van Laarhoven representation of lenses. In addition, we also discuss the partiality of derived backward transformations.

#### 9.1 Semantic Bidirectionalization

An alternative way of building bidirectional transformations other than lenses is to mechanically transform existing unidirectional programs to obtain a backward counterpart,
a technique known as bidirectionalization (Matsuda et al. 2007). Different flavors of
bidirectionalization have been proposed: syntactic (Matsuda et al. 2007), semantic (Matsuda
& Wang 2013, 2014; Voigtländer 2009a; Wang & Najd 2014), and a combination of
the two (Voigtländer et al. 2010, 2013). Syntactic bidirectionalization inspects a forward
function definition written in a somehow restricted syntactic representation and synthesizes
a definition for the backward version. Semantic bidirectionalization on the other hand treats
a polymorphic \( \text{get} \) as a semantic object, applying the function independently to a collection
of unique identifiers, and the free theorems arising from parametricity state that whatever
happens to those identifiers happens in the same way to any other inputs—this information
is sufficient to construct the backward transformation.

Our framework can be viewed as a more general form of semantic bidirectionalization.
For example, giving a function of type \( \forall a. [a] \rightarrow [a] \), a bidirectionalization engine in the
style of (Voigtländer 2009a) can be straightforwardly implemented in our framework as
follows.

\[
\text{bff} :: (\forall a. [a] \rightarrow [a]) \rightarrow (\text{Eq } a \Rightarrow \text{Lens } [a] [a])
\]
\[
\text{bff } f = \text{unlift}_\text{list} (\text{lsequence}_\text{list} \circ f)
\]

Replacing \( \text{unlift}_\text{list} \) and \( \text{lsequence}_\text{list} \) with \( \text{unliftT} \) and \( \text{lsequence} \), we also obtain the datatype
generic version (Voigtländer 2009a).

With the addition of \text{observe} and the monadic unlifting functions, we are also able to cover
extensions of semantic bidirectionalization (Matsuda & Wang 2013, 2014) in a simpler and
more fundamental way. For example, \text{liftO}_2 \text{)} and other \text{arity} observations-lifting functions
has to be a primitive function previously (Matsuda & Wang 2013, 2014), but can now be
derived from \text{observe}, \text{lift} and \( (\odot) \) in our framework.

Our work’s unique ability to combine lenses and semantic bidirectionalization results in
more applicability and control than those offered by bidirectionalization alone: user-defined
lenses on base types can now be passed to higher-order functions. For example, the XML
transformation in Section 7 (Q5 of Use Case “STRING” in XML Query Use Cases), which
involves concatenation of strings in the transformation, can be handled by our technique,
but not previously with bidirectionalization (Matsuda & Wang 2013, 2014; Voigtländer
2009a; Wang & Najd 2014). We believe that with the results in this paper, all queries in
XML Query Use Case can now be bidirectionalized. In a sense we are a step forward to the
best of both worlds: gaining convenience in programming without losing expressiveness.

The handling of observation in this paper follows the idea of our previous work (Matsuda
& Wang 2013, 2014) to record only the observations that actually happened at run-time, not
those that may. The latter approach used in (Voigtländer 2009a; Wang & Najd 2014) has the
advantage of not requiring a monad, but at the same time is not applicable to monomorphic
transformations, as the set of the possible observation results is generally infinite due to
lifted lens functions.

9.2 Functional Representation of Bidirectional Transformations

There exists another functional representation of lenses known as the van Laarhoven
representation (O’Connor 2011; van Laarhoven 2009). This representation, adopted by the
Haskell library \texttt{lens}, encodes bidirectional transformations of type $\text{Lens } A B$ as functions of the following type.

\[
\forall f. \text{Functor } f \Rightarrow (B \to f B) \to (A \to f A)
\]

Intuitively, we can read $A \to f A$ as updates on $A$ and a lens in this representation maps updates on $B$ (view) to updates on $A$ (source), resulting in a “put-back based” style of programming (Ko \textit{et al.} 2016; Pacheco \textit{et al.} 2014b). The van Laarhoven representation also has its root in the Yoneda Lemma (Jaskelioff & O’Connor 2015; Milewski 2013); unlike ours which applies the Yoneda Lemma to $\text{Lens } (\cdot V)$, they apply the Yoneda Lemma to a functor $(V, V \to (\cdot))$. Note that the lens type $\text{Lens } S V$ is isomorphic to the type $S \to (V, V \to S)$.

Compared to our approach, the van Laarhoven representation is rather inconvenient for applicative-style programming. It cannot be used to derive a \texttt{put} when a \texttt{get} is already given, as in bidirectionalization (Matsuda & Wang 2013, 2014; Matsuda \textit{et al.} 2007; Voigtländer 2009a; Voigtländer \textit{et al.} 2010, 2013; Wang & Najd 2014) and the classical view update problem (Bancilhon & Spyratos 1981; Dayal & Bernstein 1982; Fegaras 2010; Hegner 1990), especially in a higher-order setting. In the van Laarhoven representation, a bidirectional transformation $\ell :: \text{Lens } A B$, which has $\text{get } \ell :: A \to B$, is represented as a function from some $B$ structure to some $A$ structure. This difference in direction poses a significant challenge for higher-order programming, because structures of abstractions and applications are not preserved by inverting the direction of $\to$. In contrast, our construction of \texttt{put} from \texttt{get} is straightforward; replacing base type operations with the lifted bidirectional versions suffices as shown in the \texttt{unlines}_1 and \texttt{eval}_1 examples (monadification is only needed when supporting observations). Moreover, the van Laarhoven representation does not extend well to data structures: $n$-ary functions in the representation do not correspond to $n$-ary lenses. As a result, the van Laarhoven representation itself is not useful to write bidirectional programs such as \texttt{unlines}_1 and \texttt{eval}_1. Actually as far as we are aware, higher-order programming with the van Laarhoven representation has not been achieved before.

By using the Yoneda embedding, we obtained the \textit{covariant} monoidal functor $\text{Lens } S (\cdot)$ that maps lenses of type $\text{Lens } A B$ to functions $\text{Lens } S A \to \text{Lens } S B$, where $S$ is a Poset instance (Section 3.4). This is not the only way to use the Yoneda embedding. It is worth mentioning that, by using the Yoneda embedding, we can also obtain a \textit{contravariant} monoidal functor $\text{Lens } (\cdot V)$ that maps lenses $\text{Lens } A B$ to functions $\text{Lens } B V \to \text{Lens } A V$, where $V$ is a monoid satisfying certain conditions. A similar idea can be found in Rajkumar \textit{et al.} (2013), where they use contravariant functors over the category of lenses as an abstraction for bidirectional web forms, or formlenses.

### 9.3 Partiality of Backward Transformation

Unlike the original lens framework (Foster \textit{et al.} 2007) and their extensions (Bohannon \textit{et al.} 2008; Foster \textit{et al.} 2008) that guarantee the totality of backward transformations, our derived backward transformations are generally partial, similar to the case in bidirectionalization (Matsuda & Wang 2013, 2014; Matsuda \textit{et al.} 2007; Voigtländer 2009a; Voigtländer \textit{et al.} 2010, 2013; Wang & Najd 2014). Being total has the clear advantage that the backward transformations never fail, but at the same time, the totality requirement
poses strong restrictions on recursive definitions. For example, even for simple fold-like `get` functions, totality, i.e., termination, of the corresponding `put` functions is already non-trivial to guarantee, as such `puts` are usually implemented by “unfold” (Wang et al. 2010). As a result, the Boomerang framework of lenses (Bohannon et al. 2008) only supports map-like functions, leaving out other recursion patterns.

In our approach, instead of guaranteeing totality at the expense of expressiveness, we aim to reflect the partiality through types. For example, the type of `unlines` in Example 3, \( \forall s. [L\ s\ String] \rightarrow L\ s\ String \), tells that the shape of a list cannot be changed, while each list element is updatable. But this indication is not perfect. For updatable data as permitted by its type, there may still be failures coming from three sources:

- Non-linear use of updatable variables (by \( \gamma \)).
- Lifting of non-total lenses (by \( \ell \) of `lift \ell`).
- Changed observation (by \( p \) of `unliftM/unliftM2`).

The first two cases are rather predictable, even though identifying the first case would require some form of linearity analysis. For the last case, since the \( R \) monad in Section 6.2 essentially records the performed observations, there is the possibility to include diagnostic information when failure happens for improved understandability. Notice that recursion itself does not affect updatability in our framework: if a recursion does not terminate, it just means that no lens is constructed, rather than one with a partial `put`.

### 9.4 Closedness of Lifted Combinators

In Section 6.1, we looked at the lifting of lens combinators (in contrast to lifting of lenses) and mentioned that there is a closedness restriction on the argument of `liftC`, which in some cases severely restricts the programming style.

A recent work by the authors aims to address this problem in a standalone bidirectional language named HOBiT (Matsuda & Wang 2018). In HOBiT, lens combinators can be lifted to language constructs with binders, which have no closedness restriction. To achieve this, it uses an explicit variable environment for `unlift` (which roughly speaking is the counterpart of the \( s \) in \( L\ s\ a \) in this paper). The explicit nature of the environment opens it to complex manipulations, which are required for removing the closedness restriction. But it also means that an embedded implementation is no longer straightforward.

### 10 Conclusion

We have proposed a novel framework of applicative bidirectional programming, which features the strengths of lenses (Bohannon et al. 2008; Foster et al. 2007, 2008) and semantic bidirectionalization (Matsuda & Wang 2013, 2014; Voigtlander 2009a; Wang & Najd 2014). In our framework, one can construct bidirectional transformations in an applicative style, almost in the same way as in a usual functional language. The well-behavedness of the resulting bidirectional transformations are guaranteed by construction. As a result, complex bidirectional programs can be now designed and implemented with reasonable efforts.

A future step will be to extend the current ability to handle shape updates. It is important to relax the restriction that only closed expressions can be `unlift`ed to enable more practical
programming. A possible solution to this problem would be to abstract certain kind of containers in addition to base-type values, which is likely to lead to a more fine-grained treatment of lens combinators and shape updates.

Acknowledgments

We would like to thank Shin-ya Katsumata, Makoto Hamana, Kazuyuki Asada, and Patrik Jansson for their helpful comments on categorical discussions in this paper. Especially, Shin-ya Katsumata and Makoto Hamana pointed out the relationship from a preliminary version of our method to the Yoneda lemma. We would like to thank Oleg Kiselyov for his informative comments on higher-order abstract syntax. We also would like to thank the anonymous reviewers of this paper for their helpful comments.

This work is partially supported by JSPS KAKENHI Grant Numbers 24700020, 25540001, 15H02681, and 15K15966, and the Grand-Challenging Project on the “Linguistic Foundation for Bidirectional Model Transformation” of the National Institute of Informatics. The work is partly done when the first author was at the University of Tokyo, Japan, and when the second author was at University of Kent, UK.

A Proof of Lemma 1

The proof is based on free theorems (the standard binary version) (Reynolds 1983; Voigtländer 2009b; Wadler 1989).

The difficulty of the proof lies in the treatment of `unlift`. Usually, a proof based on free theorems is done by encoding relationship between two arguments (e.g., `ℓ` and `idL`) of a
polymorphic function to a relation, and then by using the fact that such a polymorphic function preserves the relation. Here, in addition, we have to prove that lift and unlift preserve the relation because \( f \) can use lift and unlift internally. Our proof obligation for unlift is that two arbitrary polymorphic functions \( g_1 \) and \( g_2 \) that preserve the relation satisfies that \( g_1 \; id_L = g_2 \; id_L \). That is, it might seem that the relation must contain the pair \((\ell, id_L)\) and must be diagonal at the same time, which appears contradictory. Very roughly speaking, this difficulty comes from the fact that we have to encode two different goals, \( f \; \ell = f \; id_L \circ \ell \) and \( g_1 \; id_L = g_2 \; id_L \), where \( f \), \( g_1 \) and \( g_2 \) are of the same polymorphic type, to one relation. To overcome the problem, we use the polymorphic nature of \( s \) and the fact that such a relation can depend on the choice of \( s \), which is the reason why our proof becomes tricky.

### A.1 Free Theorems (Binary Version)

We write \( \mathcal{R} :: A_1 \leftrightarrow A_2 \) if \( \mathcal{R} \) is a binary relation between \( A_1 \) and \( A_2 \). For relations \( \mathcal{R} :: A_1 \leftrightarrow A_2 \) and \( \mathcal{R'} :: B_1 \leftrightarrow B_2 \), we abuse the notation to write \( \mathcal{R} \to \mathcal{R'} :: (A_1 \to B_1) \leftrightarrow (A_2 \to B_2) \) for the relation \( \{(f_1, f_2) \mid \forall(x_1, x_2) \in \mathcal{R}, (f_1(x_1), f_2(x_2)) \in \mathcal{R'}\} \), and \( (\mathcal{R}, \mathcal{R'}) :: (A_1, B_1) \leftrightarrow (A_2, B_2) \) for \( \{(((x_1, x_1), (x_2, y_2)) \mid (x_1, y_2) \in \mathcal{R}, (y_1, x_2) \in \mathcal{R'}\} \).

We introduce a (binary) relational interpretation \( [\tau]_\rho^2 \) of types, where \( \rho \) is a mapping from type variable to binary relations, as follows.

\[
\begin{align*}
[a]_\rho^2 &= \rho(a) \\
[B]_\rho^2 &= \{(e, e) \mid e :: B\} \quad \text{if } B \text{ is a base type} \\
[T_1 \to T_2]_\rho^2 &= [T_1]_\rho^2 \to [T_2]_\rho^2 \\
[(T_1, T_2)]_\rho^2 &= ([T_1]_\rho^2, [T_2]_\rho^2) \\
[\forall \alpha. T]_\rho^2 &= \left\{(u, v) \mid \forall \mathcal{R} :: S_1 \leftrightarrow S_2, (u_{S_1}, v_{S_2}) \in [T]_\rho^2\right\}
\end{align*}
\]

Here, \( \rho[a \to \mathcal{R}] \) is an extension of \( \rho \) with \( a \to \mathcal{R} \). If \( \rho = \emptyset \), we sometimes write \([T]_\emptyset^2 \) instead of \([T]_\emptyset^2 \). Similarly to the unary case, we write \([\forall \alpha. \tau]_\emptyset^2 \) as \( \forall \mathcal{R}. \mathcal{F} \) where \( \mathcal{F} \) is the interpretation \([\tau]_\emptyset^2\). For a base type \( B \), we also write \( [B]_\emptyset^2 \).

Then, parametricity states that, for a closed term \( f \) of a closed type \( \tau \), \( (f, f) \in [\tau]_\rho^2 \) holds. Free theorems are theorems obtained by instantiating parametricity.

Next, we introduce the binary-version of relational action (Voigtländer 2009b).

**Definition 6 (Binary Relational Action).** For type constructors \( \kappa_1 \) and \( \kappa_2 \), \( \mathcal{F} \) is called a relational action between \( \kappa_1 \) and \( \kappa_2 \), denoted by \( \mathcal{F} :: \kappa_1 \leftrightarrow \kappa_2 \), if \( \mathcal{F} \) maps any relation \( \mathcal{R} :: \tau_1 \leftrightarrow \tau_2 \) for every pair of closed types \( \tau_1 \) and \( \tau_2 \) to \( \mathcal{F} \mathcal{R} :: \kappa_1 \tau_1 \leftrightarrow \kappa_2 \tau_2 \).

Accordingly, the relational interpretations are extended as:

\[
\begin{align*}
[k]_\rho^2 &= \rho(\kappa) \\
[\tau_1 \tau_2]_\rho^2 &= [\tau_1]_\rho^2 \bowtie [\tau_2]_\rho^2 \\
[\forall \kappa. \tau]_\rho^2 &= \left\{(u, v) \mid \forall \mathcal{F} :: \kappa_1 \leftrightarrow \kappa_2, (u_{\kappa_1}, v_{\kappa_2}) \in [\tau]_\rho^2\right\}
\end{align*}
\]

Parametricity holds also for this relational interpretation (Bernardy et al. 2012; Vyntios & Weirich 2010). Here, \( \kappa \), \( \kappa_1 \) and \( \kappa_2 \) are type constructors of kind \( * \to * \), and thus the
Let \( f \) be a function of the giving types. Let \( f \) comes from the two different contexts where \( F \rightarrow S \rightarrow R \). Notice that we do not require that \( f \) satisfies the required conditions in Lemma 5 are fulfilled. Then, by the lemma, we obtain \( f \) as a function of appropriate types belongs to \( Lens S \). Thus, we obtain \( f \) satisfies the required conditions in Lemma 5 and \( f \) satisfies the required conditions in Lemma 5 for any \( l_1 \) and \( l_2 \) with appropriate types. The complication of \( f \)’s definition comes from the two different contexts where \( f \) can be instantiated: (1) \( f \) is a function of type \( \forall s. \text{Lens } s A \rightarrow \text{Lens } s B \) in which \( \text{Lens} \) is abstract. Suppose that \( \mathcal{F} : \kappa_1 \leftrightarrow \kappa_2 \) is a relational action satisfying the following conditions.

- \( \text{lift, lift} \in \forall \mathcal{T}.\forall !. \text{Lens } \mathcal{T} \mathcal{U} \rightarrow (\forall s. \mathcal{F} \mathcal{S} \mathcal{R} \rightarrow \mathcal{F} \mathcal{S} \mathcal{U}) \).
- \( \text{unlift, unlift} \in \forall \mathcal{T}.\forall !. (\forall s. \mathcal{F} \mathcal{S} \mathcal{R} \rightarrow \mathcal{F} \mathcal{S} \mathcal{U}) \rightarrow \text{Lens } \mathcal{T} \mathcal{U} \).

Then, \((f, f) \in \forall s. \mathcal{F} \mathcal{S} A \rightarrow \mathcal{F} \mathcal{S} B \).
Case: \((\text{lift}, \text{lift}) \in \forall \mathcal{T}. \forall \mathcal{U}. \text{Lens } \mathcal{T} \mathcal{U} \rightarrow (\forall S. \mathcal{F} S \mathcal{T} \rightarrow \mathcal{F} S \mathcal{U})\). Let \(\mathcal{T} :: A_1 \leftrightarrow A_2\) and \(\mathcal{U} :: B_1 \leftrightarrow B_2\) be relations. Let \(x_1 :: \text{Lens } A_1 B_1\) and \(x_2 :: \text{Lens } A_2 B_2\) be lenses. Let \(S :: C_1 \leftrightarrow C_2\) be a relation. Let \((z_1, z_2)\) be lenses such that \((z_1, z_2) \in \mathcal{F} S \mathcal{T}\). Then, by Lemma 4, we have \((\text{lift } x_1 z_1, \text{lift } x_2 z_2) = (x_1 \delta z_1, x_2 \delta z_2) \in \mathcal{F} S \mathcal{U}\).

Case: \((\text{unlift}, \text{unlift}) \in \forall \mathcal{T}. \forall \mathcal{U}. (\forall S. \mathcal{F} S \mathcal{T} \rightarrow \mathcal{F} S \mathcal{U}) \rightarrow \text{Lens } \mathcal{T} \mathcal{U}\). Let \(\mathcal{T} :: A_1 \leftrightarrow A_2\) and \(\mathcal{U} :: B_1 \leftrightarrow B_2\) be relations. Let \(g_1\) and \(g_2\) be functions satisfying \((g_1, g_2) :: \forall S. \mathcal{F} S \mathcal{T} \rightarrow \mathcal{F} S \mathcal{U}\). Take \(S = \mathcal{T}\). Suppose \(\mathcal{T} = \emptyset :: S_1 \leftrightarrow S_2\). Then, we trivially have \((g_1 \text{id}_L, g_2 \text{id}_L) \in \text{Lens } \emptyset \mathcal{U}\).

Recall that \((\ell_1, \ell_2) \in \text{Lens } \emptyset \mathcal{U}\) for any \(\ell_1\) and \(\ell_2\) with appropriate types. Suppose \(\mathcal{T} \neq \emptyset :: S_1 \leftrightarrow S_2\). Then, we have \((\text{id}_L, \text{id}_L) \in \mathcal{F} \mathcal{T} \mathcal{T}\) and thus \((g_1 \text{id}_L, g_2 \text{id}_L) \in \mathcal{F} \mathcal{T} \mathcal{U}\). Since we have assumed \(\mathcal{T} \neq \emptyset :: S_1 \leftrightarrow S_2\), we have \((g_1 \text{id}_L, g_2 \text{id}_L) \in \text{Lens } \mathcal{T} \mathcal{U}\). \(\square\)
