Correspondence to: Professor R. J. Hinchliffe, Bristol Surgical Trials Centre, Bristol Medical School, University of Bristol, Bristol BS8 2PS, UK (e-mail: robert.hinchliffe@bristol.ac.uk)

Background: Case series and a post hoc subgroup analysis of a large randomized trial have suggested a potential benefit in treating ruptured abdominal aortic aneurysms (rAAAs) using endovascular aneurysm repair (EVAR) with local anaesthesia (LA) rather than general anaesthesia (GA). The uptake and outcomes of LA in clinical practice remain unknown.

Methods: The UK National Vascular Registry was interrogated for patients presenting with rAAA managed with EVAR under different modes of anaesthesia between 1 January 2014 and 31 December 2016. The primary outcome was in-hospital mortality. Secondary outcomes included: the number of centres performing EVAR under LA; the proportion of patients receiving this technique; duration of hospital stay; and postoperative complications.

Results: Some 3101 patients with rAAA were treated in 72 hospitals during the study: 2306 underwent an open procedure and 795 had EVAR (LA, 319; GA, 435; regional anaesthesia, 41). Overall, 56 of 72 hospitals (78 per cent) offered LA for EVAR of rAAA. Baseline characteristics and morphology were similar across the three EVAR subgroups. Patients who had surgery under LA had a lower in-hospital mortality rate than patients who received GA (59 of 319 (18.5 per cent) versus 122 of 435 (28.0 per cent)), and this was unchanged after adjustment for factors known to influence survival (adjusted hazard ratio 0.62, 95 per cent c.i. 0.45 to 0.85; \( P = 0.003 \)). Median hospital stay and postoperative morbidity from other complications were similar.

Conclusion: The use of LA for EVAR of rAAA has been adopted widely in the UK. Mortality rates appear lower than in patients undergoing EVAR with GA.

Introduction

Without emergency surgical intervention, ruptured abdominal aortic aneurysm (rAAA) is usually fatal. Global experience with endovascular aneurysm repair (EVAR) for elective abdominal aortic aneurysm (AAA) has led to its increasing use in the emergency setting.1,2 Comparative outcomes between conventional open and endovascular repair for ruptured AAA (rEVAR) have been assessed in one case series3 and four RCTs4–7. A recent individual-patient meta-analysis8 of three RCTs that compared EVAR with open repair for rAAA reported that women might benefit more from the EVAR approach and that patients are discharged sooner after EVAR, although survival at 90 days was similar in the two groups. Despite this, earlier discharge from critical care, shorter hospital stay, and a higher proportion discharged directly home in the EVAR group means that the EVAR approach is likely to gain further support for its use in rAAA, especially in specialist centres. Furthermore, the EVAR approach for rAAA may allow treatment of more elderly patients and those with significant co-morbidities who would not be considered feasible candidates for open surgery.2

A case series3 of 20 patients, published in 2002, demonstrated the feasibility of performing rEVAR under local anaesthesia (LA). A subsequent post hoc subgroup analysis of a cohort of 186 patients who underwent rEVAR in the IMPROVE (Immediate Management of the Patient with Rupture: Open Versus Endovascular repair) trial9 demonstrated a significantly reduced 30-day mortality rate for patients operated on under LA compared with surgery.
under general anaesthesia (GA): odds ratio 0.27 (95 per cent c.i. 0.10 to 0.70), after adjustment for potential confounding. The magnitude of benefit observed with LA in the IMPROVE trial warrants further investigation and, if replicated in a well conducted RCT, would suggest that LA should become the standard of care in rEVAR. However, at this stage little is known about how applicable this technique might be to patients in everyday clinical practice and how widely the technique has been adopted across the UK.

The UK National Vascular Registry (NVR), which captures data on more than 90 per cent of AAA procedures, provides a unique opportunity to examine practice and outcomes in a real-world setting, and includes centres that may not have contributed patients to the IMPROVE trial. The aim of this study was to quantify the uptake of LA for rEVAR across all UK vascular centres and evaluate whether the benefit of LA observed in the IMPROVE trial has been replicated in everyday clinical practice.

**Methods**

**National Vascular Registry**

The NVR was commissioned by the Healthcare Quality Improvement Partnership (HQIP), as part of the National Clinical Audit and Patient Outcomes Programme, to measure quality of care and outcomes in patients undergoing vascular interventions in National Health Service (NHS) hospitals. Data submission is mandatory and forms part of the revalidation of vascular surgeons. Data are assessed for consistency, including range checks, and also comparison of case ascertainment with the Hospital Episode Statistics (HES) data set, to which all NHS Trusts in England are obliged to contribute for financial probity. Equivalent checks were applied to data for patients operated on in Scotland (Scottish Morbidity Record, SMR01), Wales (Patient Episode Database for Wales) and Northern Ireland (Hospital Activity Statistics). The NVR is the largest recognized register of AAA procedures in the UK. Permission was obtained from HQIP for the NVR

to release anonymized patient data under a data-sharing agreement signed between HQIP and the University of Bristol.

Study population

The study population comprised patients undergoing repair of a rAAA in the UK between 1 January 2014 and 31 December 2016. The registry classifies each procedure as open, EVAR, complex EVAR, revision open, revision EVAR or endovascular aneurysm sealing (EVAS), and the AAAs were grouped into asymptomatic, symptomatic unruptured, ruptured, aortic transection, acute dissection or chronic dissection. The EVAR and EVAS procedures were combined. The following were excluded: aortic transections, acute and chronic dissections, thoracic aneurysms and thoracoabdominal aneurysms. Case ascertainment for the NVR for the period 2014–2016 was 91 per cent for rAAA.

Mode of anaesthesia

Modes of anaesthesia captured in the NVR include GA, LA and regional anaesthesia (RA). The NVR does not identify procedures that were initiated under LA only but then converted to GA (or RA) later in the procedure. Such procedures are coded as GA or RA, as appropriate.

Data collection

Data items included in the NVR and available for analysis are summarized in Appendix S1 (supporting information). The Hardman index for predicting the risk of an adverse outcome is not captured in the NVR. However, four of the five factors used to derive the index are included. Therefore, a modified Hardman index was derived based on age, haemoglobin, serum creatinine and ECG findings only (excluding data on loss of consciousness).

Study outcomes

The primary outcome of this study was in-hospital mortality. Hospital discharge was defined as discharge from the hospital in which the vascular surgical procedure was performed. Patients could be discharged home, to a referring hospital, or to a rehabilitation hospital. Secondary clinical outcomes included postoperative length of hospital stay (LOS), ICU admission rate, duration of ICU stay and postoperative complications. Secondary process outcomes included uptake of EVAR for rAAA across centres and use of LA for these procedures.

Statistical analysis

Continuous data are summarized as mean(s.d.) values (or median (i.q.r.) if the distribution is skewed). Categorical
data are summarized as a number and percentage. Patients undergoing EVAR were grouped by the type of anaesthesia received: LA, GA or RA. Standardized mean differences were calculated to quantify the differences between baseline characteristics and the aortic morphology of patients undergoing EVAR under GA and LA.

Cox proportional hazards regression was used to compare in-hospital mortality by mode of anaesthesia. Survivors were censored at hospital discharge. The analysis was adjusted for modified Hardman index, ASA fitness grade, maximum AAA diameter and sex, and centre fitted as a frailty term. Kaplan–Meier curves were constructed to estimate mortality rates to 30 days. Secondary outcomes are described, but not compared formally. For duration of ICU and hospital stay, patients who died before hospital discharge were censored at death.

Missing data are described in table footnotes. Multiple imputation was used to account for missing data in analyses. Fifty-two imputed data sets were generated and the results combined using Rubin’s rules. Sensitivity analyses with missing data are described, but not compared formally. For duration of ICU and hospital stay, patients who died before hospital discharge were censored at death.

Missing data are described in table footnotes. Multiple imputation was used to account for missing data in analyses. Fifty-two imputed data sets were generated and the results combined using Rubin’s rules. Sensitivity analyses with missing data items for the Hardman index were assigned 0 points (sensitivity analysis 1) or 1 point (sensitivity analysis 2). All analyses were performed in Stata® version 15.1 (StataCorp, College Station, Texas, USA).

Local anaesthesia for endovascular repair of ruptured abdominal aortic aneurysm

Results

Between January 2014 and December 2016, the NVR collected data on 20,936 patients undergoing AAA repair, 13,354 (63.8 per cent) of whom underwent EVAR. Of these 13,354 patients, 795 (6.0 per cent) had rEVAR (Fig. 1). The majority of patients undergoing rEVAR received GA (435, 54.7 per cent), with 319 (40.1 per cent) having LA and 41 (5.2 per cent) RA.

rEVAR procedures were carried out across 72 hospitals, 56 (78 per cent) of which performed at least one procedure under LA. The hospitals that used LA for rEVAR were the higher-volume centres carrying out a median of 47.0 EVAR and 15.2 rAAA procedures each year, compared with a median of 26.7 EVAR and 7.9 rAAA procedures in the non-LA centres (Fig. 2a, Table S1, supporting information). Across the 56 centres performing rEVAR under LA, a median of 40.0 (i.q.r. 22.6–60.0) per cent of procedures used LA, and the rate was similar for procedures performed during standard working hours (08.00 to 17.00 hours Monday to Friday) and procedures performed out of hours (Fig. 2b; Table S2, supporting information).

Patient characteristics

Mean age was 79 years in the LA and RA groups and 77 years in the GA group; the majority of patients were men (Table 1). Over 85 per cent of patients had co-morbidities and 15 per cent were moribund (ASA grade V). Of patients with data, only 16.6 per cent had none of the four risk factors included in the modified Hardman index, and 12.3 per cent had at least three risk factors. The mean maximum AAA diameter exceeded 72 mm in all groups. Characteristics of patients in the LA and GA groups were similar, as indicated by the small mean differences (less than 0.2) for most factors examined.

Patients undergoing open surgery for rAAA were slightly younger and had fewer risk factors than those having rEVAR (Table S3, supporting information).

Outcomes

Overall, 187 of 795 patients (23.5 per cent) undergoing rEVAR died before hospital discharge (Table 2). The in-hospital mortality rate was highest in the GA group, 28.0 per cent, followed by 18.5 per cent in the LA group and 15 per cent in the RA group. After adjustment, the risk of death in patients having rEVAR under LA was 38 per cent lower than the risk under GA (adjusted hazard ratio 0.62, 95 per cent c.i. 0.45 to 0.85; \( P = 0.003 \)).

Values in parentheses are percentages unless indicated otherwise; *values are median (i.q.r.). †Estimated using survival methods with patients censored if they died in hospital; ‡excludes patients who died in theatre.

LA, local anaesthesia; GA, general anaesthesia; RA, regional anaesthesia; LOS, length of hospital stay.

Discussion

The main finding of this contemporary UK-based study is that LA for endovascular repair of rAAA is associated with reduced in-hospital mortality compared with GA.

Four RCTs comparing open and endovascular repair have reported broadly comparable outcomes between the two approaches, and EVAR is now an established treatment strategy for rAAA. This has led to the emergence of rAAA repair under LA and RA that was previously not possible.
Any registry is limited by the completeness and quality of its data. The NVR is externally validated against HES data in England (and equivalent routine data for Scotland, Wales and Northern Ireland), and any discrepancies are raised at a central level. Case ascertainment rates continue to improve; over the 3 years from 2014 to 2016 it was 91 per cent for rAAA. Nevertheless, the observed mortality rate was lower than might be expected for this patient group, and the potential for reporting bias remains. The NVR data collection system includes extensive checks to ensure that the values entered are valid (range checks and cross-validation on various fields), and individual hospitals are asked to check data that appear spurious. Thus the internal validity of the registry is high. Additionally, multiple imputation methods were applied to ensure all cases were included in the analyses and not dropped owing to missing data. The NVR was established as part of the National Clinical Audit and Patient Outcomes Programme, and was not designed primarily for research. Despite its limitations, registries such as the NVR are a vital tool to audit the safety of novel treatment approaches in rAAA and to monitor that trial outcomes are being replicated in routine practice.

Emergency EVAR can be undertaken under different modes of anaesthesia. However, there is a lack of standardization and consistency in how anaesthetic techniques are defined. The complexity increases when sedation is used alongside LA or RA. The recording of anaesthesia in the NVR does not include whether or not sedation was used. The boundary between deep sedation and GA is fluid, and both definitions can include patients whose airway and ventilatory function might require support. It is not known how many of the procedures in the present study cohort from the NVR were started as an LA procedure and converted to GA. This may introduce bias and is a potential weakness that was not possible to address due to the limitations of the database. In the IMPROVE trial, 16 per cent of patients treated initially under LA were converted to GA, and the outcomes of this group were similar to those of the GA group. There are other potential confounders that this study could not address as the data were not available. For example, the level of haemodynamic instability may affect both the choice of anaesthesia and outcomes. If the proportion of more haemodynamically stable patients was higher in the LA group this would favour LA. Furthermore, centres using LA had higher case volumes than those not using LA, and there might be unknown centre-specific characteristics such as experience of LA and secondary transfers that could influence outcome.

Mortality from emergency surgery for rAAA remains high, with variation among different healthcare systems and countries. Furthermore, the burden of morbidity is significant in survivors. Therefore, even a small reduction in perioperative mortality could have a dramatic effect.
Local anaesthesia for endovascular repair of ruptured abdominal aortic aneurysm

This study provides further evidence of the benefit of LA for patients undergoing emergency EVAR for rAAA.

Acknowledgements

The authors express their gratitude to all the vascular surgeons and patients who have contributed data to the NVR. Special thanks go to S. Waton from the Clinical Effectiveness Unit, Royal College of Surgeons of England, for conducting the data retrieval from the NVR.
