Abstract

Nitrogen-vacancy ($NV^-$) defects embedded in nanodiamond have attracted attention for their useful photonic and spin properties, and their exceptional photo-stability. Efficiently detecting nanodiamonds that possess colour centres and discriminating from any background fluorescent contamination is essential for nanodiamond-based technologies, and so necessitates the detection of both the nanoparticle and the fluorescent signature. However, optically detecting small nanodiamonds ($< 40 \text{ nm}$) proves difficult due to the low absorption and scattering cross section of nanodiamonds. Here we demonstrate an all optical method capable of simultaneous colocalising scattered signal from individual nanodiamonds ($\approx 10 \text{ nm}$) with the fluorescent signature from $NV^-$ centres.
Keywords

Cross-Polarisation Imaging, Nanodiamond, $NV^-$ centers, Single Particle Detection, Single Molecule Detection, Colocalisation

The applications for nanodiamonds (ND) range from single photon sources for quantum technologies,\textsuperscript{1,2} to biocompatible, photostable trackers for biological labelling,\textsuperscript{3,4} to nanosensing magnetic field probes for nuclear magnetic resonance spectroscopy.\textsuperscript{5} However, these applications usually require that the selected NDs include a colour centre, an optically active defect in the diamond lattice; the most commonly desirable of which is a negatively charged nitrogen-vacancy ($NV^-$) defect. $NV^-$ centres can be fabricated in ND by ion bombardment to create defects that, followed by annealing, allow the colour centre to form by a diffusive process. The resultant defect is an extremely photostable emission centre that acts as a single photon emitter displaying quantum behaviour up to room temperature.\textsuperscript{6} To develop technologies that exploit these properties, it is essential that there is an effective and reliable method for identifying NDs that possess such $NV^-$ centres. Moreover for their application in quantum technologies, a complete characterisation of the individual or ensemble properties of the embedded colour centres is required.

To characterise fluorescent nanoparticles such as nanodiamonds, one can employ techniques such as NSOM,\textsuperscript{7–10} AFM,\textsuperscript{11} TEM,\textsuperscript{12} confocal microscopy\textsuperscript{13} or these tools in combination.\textsuperscript{14} Regardless of the approach, it is important to correlate both the nanodiamond crystal and the fluorescent signature of any colour centre of interest in the same nanoparticle. This ensures that fluorescence arises from the NDs themselves rather than single molecules or other surface contaminants on the glass substrate, as was the case in a recent retraction of a quantum dot study published in Nature.\textsuperscript{15} Ideally this two-component characterisation is done rapidly using the same instrument to reduce ambiguity and the time taken to process the sample. However when working with NDs, direct optical detection of the crystals below 40 nm diameter remains difficult due to the extremely low absorption cross section of diamond,\textsuperscript{16,17} which prevents the use of particle detection techniques that rely on non-
linear absorption effects or photo-thermal heating. Recently, a group from Cardiff University showed highly effective detection of large ND crystals through Coherent anti-Stokes Raman scattering, though the sensitivity of this process is limited to detecting NDs with radius $> 27$ nm at the reported illumination powers and integration times.$^{14}$

Motivated by this current limitation in the field, we apply our recently introduced technique, Interferometric Cross-Polarization Microscopy (ICPM), to the imaging of single ND’s while simultaneously detecting the fluorescent signal from colour centres. In doing so, we demonstrate an all-optical approach for the characterisation of individual nanodiamond crystals containing \(NV^-\) centres. Furthermore, we achieve these detection sensitivities while using low excitation powers (25 \(\mu\)W on the sample) using an inexpensive laser system, in contrast to techniques such as four wave mixing (FWM).$^{14}$ Operating at low powers enables the simultaneous detection of single molecule fluorescence; making the technique an attractive option for rapidly identifying and rejecting fluorescent signal not originating from nanocrystals of interest. Furthermore, this makes the technique applicable to less photostable fluorophores or potentially to the study of shallow \(NV^-\) centres which can also exhibit bleaching.$^{18}$

ICPM$^{19}$ is an interferometric, point-scanning, confocal-like detection method with an optical sectioning capability on par with conventional confocal microscopy.$^{20}$ Due to operating in a crossed polarized regime, the technique achieves detection sensitivities limited solely by the shot noise of the scattered signal and has demonstrated the detection of gold nanoparticles down to 5 nm at extremely low excitation powers( $< 1 \mu$W) demonstrating its sensitivity.$^{19,21}$ Within the microscope, as schematically depicted in Fig. 1(a), a coherent laser source is incident on a 50:50 beam splitter to generate a signal and reference branch. To enable heterodyne detection, the reference branch is frequency offset by a pair of acousto-optic modulators before passing through a half-wave plate and a Glan-Thompson Polarizer (GTP) oriented to produce y-polarized light. The signal branch is polarized by a second GTP to produce x-polarized light and focused \(via\) an oil immersion, high numerical aperture (NA
Figure 1: (a) Schematic diagram of Interferometric Cross-Polarization Microscopy (ICPM). A coherent source is split into frequency offset, orthogonally polarized signal and reference paths enabling heterodyne detection of the scattered signal. Light in the signal branch is focussed onto the sample by a high NA (1.45) objective, then recollimated by a second objective (NA 0.9) before recombining with the reference branch on a photodiode detector. (b-d) Strong focusing of linearly polarized light projects the polarization state across all three axes according to certain spatial distributions (1 µm × 1 µm). Only light scattered with like-polarization state to the reference path is interferometrically enhanced, producing the characteristic four-leaf clover scattering distribution of ICPM.
1.45) illumination objective onto a size 1.5H (Marienfeld) glass coverslip. The focused light is re-collimated by a collection objective (NA 0.9) and overlapped with the reference branch by a second beam splitter, prior to focusing on a photodiode. The optical sectioning is defined by the interference of planar waves between the two branches; only light imaged from the focal region will interfere at the recombination beam splitter. Fluorescent signal is collected from the sample through the illumination objective and detected via a dichroic beam splitter (Semrock Di01-T405/488/532/647) on an avalanche photodiode (APD) with a dark count rate of less than 100 cts/second (Perkin Elmer SPCM-AQRH-14).

According to the theory of strong electromagnetic focussing (the vectorial diffraction regime), a linearly polarized beam focused by high NA objectives projects a linear polarization state along all three axes, with a spatial and intensity distribution in the focal plane as seen in Fig. 1(b-d).\textsuperscript{22–25} If undisturbed, the polarization distribution at the focus is re-transformed into linear polarization by the collection objective and no interferometric signal is detected on the photodiode; as interference does not occur between orthogonally-polarized beams. In the case where an object with an electric dipole moment is present in the focus, light is scattered to the far field from all three polarization directions; proportionally to their representation in the focus and the dipole alignment. However, only forward scattered y-polarized light is interferometrically enhanced by the like-polarized reference branch; producing the signature four leaf clover scattering distribution observed when scanning a nanoparticle through the focus. This scattering distribution strongly reflects the corresponding component of the polarization at the focus, see Fig1(c), albeit with the side lobes suppressed due to interference with a Gaussian reference beam.\textsuperscript{21}

To prepare the ND sample, a coverslip is cleaned and surface charged by a 10 minute 1:2 part Sulfuric-Nitric acid bath with two subsequent 10 minute baths in double deionised water. After diluting a solution of expected 20 nm diameter NDs, as purchased from Adámas Nanotechnologies, Inc., the NDs were drop deposited onto the coverslip and after waiting two minutes excess solution was removed by exposure to an \(N_2\) stream. To test both our
deposition procedure and the size distribution of the deposited nanoparticles the sample was imaged using AFM. A typical AFM image (3.5x2.5um area) is presented in figure 2(a). This demonstrates a size different from that quoted by the manufacturer as we measure an mean height of $10 \pm 2\text{nm}$ with a low spatial concentration of larger particles as supported by a histogram of peak particle heights for 108 particles, figure 2(b). The inter-particle distance observed is typically $> 1\mu m$ as achieved by choice of solution concentration, ensuring the sample is sufficiently monodisperse to allow single particles to be imaged under a diffraction limited approach.

A similarly prepared sample was imaged on the ICPM using an excitation wavelength of 532 nm while simultaneously collecting fluorescence on an APD with a 640 nm long pass filter (LPF). A typical image of the scattered optical amplitude as a function of position is shown in Figure 3(a) taken at 25 µW incident on the coverslip. The observed variation of peak intensities is consistent with the range of particle sizes observed under AFM as the scattered optical amplitude scales with $D^3$ in our approach. Here we clearly identify the characteristic four leaf clover scattering distribution associated with imaging under crossed polarization resulting from the field distribution in Fig. 1(c). A similar inter-particle distance to the AFM data is observed, showing that it is indeed possible to detect 10 nm nanodiamond.
Figure 3: (a) A 532 nm illumination source is polarized in the y-direction and an image of the scattered amplitude and (b) fluorescent signature of 10 nm ± 2 nm diamond nanoparticles is produced for 25 μW excitation power. The excitation polarization is then rotated to the x-direction and the (c) scattered amplitude and (d) fluorescence are collected. (e) The scattering and fluorescent data is assigned to the G and R channels of an overlaid image to show colocalisation under (e) y-polarized and (f) x-polarized incident illumination.
For an incident polarization direction along the y-axis, figure 3(b) shows an example of the corresponding fluorescent image taken simultaneously to the scattering image in figure 3(a). Here we see an elongated diffraction limited spot along the polarization direction in the fluorescent channel as expected from a strongly focused linearly polarized beam; Fig. 1(b). To probe the dipole-nature of the NV$^-$ centre, which should absorb optimally when aligned with the polarization direction, a second image was taken with the incident and reference polarization rotated by 90 degrees$^{23}$ figure 3(c,d). Dashed boxes (i,ii) in figure 3(b,d) highlight the fluorescent signature of two nanodiamonds that display peak fluorescence 122 cts/px and 168 cts/px respectively under y-polarized illumination and 189 cts/px and 131 cts/px under x-polarized illumination. These trends, which are repeated over multiple images, indicate that there is preferred polarization alignment between particles for photon-emission.$^{23}$ In this way, we can observe the dipolar behaviour of individual NDs through colocalised detection between scattered and fluorescent signals at the single molecule level.

False colour images for orthogonal polarization illuminations, Fig 3(e,f), reveal that there is a fluorescent population, likely single fluorophores, without associated scattering objects; emphasising the need for simultaneous detection of both particle and fluorescent signature. This fluorescent background is not observed when a sample is imaged following the same protocol without the ND solution showing that this signal originates from the solution. The scattering signal in Fig 3(f) displays the first order side lobes to the left of the cloverleaf consistently over all imaged particles. This is due to shifting the Glan-Thompson Polarizer which slightly changes the overlap between signal and reference path, and in principle does not limit colocalisation as the scattered signal from the Fig 3(e) can be used to colocalise against.

In our current work we are mainly interested in demonstrating an effective optical correlation technique for nanoparticles, with NV$^-$ centres embedded in ND proving an excellent test-case. We can determine the relative fraction of nanodiamond that contain NV$^-$ centres, by measuring only two orthogonal excitation polarizations as we will discuss shortly.
Here, ICPM is configured to use linearly polarized beam paths for the high extinction ratios necessary for sensitive scattering detection, though in principle it is possible to illuminate with circularly polarized light to optimally excite an NV$^-$ centre at arbitrary in-plane orientation. To fully characterise the 3D orientation of the NV$^-$ centre dipole moment, the incident polarization angle needs to be incrementally advanced through the full $2\pi$ phase space or the NV$^-$ centre needs to be excited under radially polarized light; this additional step is beyond the scope of this paper, but the required methodology is well established and will not pose a problem for future implementations of this technique as a characterisation step for quantum devices.

To identify NDs with fluorescent colour centres, a tracking algorithm is developed that utilises the high detection sensitivity of scattered detection under ICPM to sample only particles which present a characteristic four-lobed scattering signal. This ensures that fluorescence signatures that arise from fluorescent molecules or other contaminants are not considered in the analysis; as all fluorescent peaks originating from an NV$^-$ are required to colocalise well with a scattering object. For the amplitude component of the scattered signal, local scattering maxima are identified and grouped with all neighbours within 0.4 micron. Clusters of local maxima comprised of exactly four maxima that also fit well to the spatial dimensions of the cloverleaf, as modelled in earlier works, are considered singular scattering objects; all other scattered signals are rejected. To help eliminate clusters or false positives from nanoparticle contamination, scattering signals outside a window of expected amplitude responses may be removed.

Local maxima in the fluorescence data are located and paired to scattering particles by location; within a 0.1 micron tolerance of the centre of the four-lobe pattern. In the case where no fluorescence signal can be colocalised with a scatterer, the average fluorescence value of the immediate area is assigned instead, which corresponds to the background fluorescence of the sample. The dipole-like behaviour of an NV$^-$ centre is best described by a pair of degenerate orthogonal dipoles, visualised as the $x'$ and $y'$ axes of an arbitrarily
oriented coordinate system \((x', y', z')\) in Fig. 4. To remove the incident polarization direction 
dependence when aiming to colocalise scattered and fluorescent signals, a second image with 
incident polarization orthogonal to the first is therefore also collected. Fluorescent signatures 
from the orthogonal polarization image are similarly assigned to identified scattering objects 
after accounting for any small shift between subsequent measurements induced by rotating 
the Glan-Thompson Polarizer.

Figure 4: The dipole-like behaviour of an \(NV^-\) centre may be described as a pair of degenerate orthogonal dipoles.\(^{28}\) A rotated coordinate system \((x', y', z')\) (red) is defined relative to the laboratory frame \((x, y, z)\) (black) in terms of Euler angles. For convenience, the two dipoles of an \(NV^-\) centre are assigned with respect to \((x', y', z')\) such that \(\vec{\rho}_1 = (1, 0, 0)\) and \(\vec{\rho}_2 = (0, 1, 0)\).

To combine these data sets, we consider the two degenerate orthogonal dipoles \((\vec{\rho}_1, \vec{\rho}_2)\) 
of an \(NV^-\) centre in terms of Euler angles with respect to the laboratory frame following 
Fig. 4 as;

\[
\vec{\rho}_1 = \begin{pmatrix}
\cos(\alpha) \cos(\gamma) - \sin(\alpha) \cos(\beta) \sin(\gamma) \\
\sin(\alpha) \cos(\gamma) + \cos(\alpha) \cos(\beta) \sin(\gamma) \\
\sin(\beta) \sin(\gamma)
\end{pmatrix}
\]  

(1)
For linearly polarized excitation, the polarized field at the focus is predominantly parallel to the light entering the illumination objective. Assuming both dipoles interact equally with an electric field, \(^{27,28}\) for x-polarized excitation the fluorescent signal, \(K\), can be shown to scale as;

\[
K_x = 2 \sum_i |\vec{\rho}_i \cdot \vec{E}|^2 = E_x[1 - \sin^2 \alpha \sin^2 \beta]
\]

And for y-polarized excitation as;

\[
K_y = 2 \sum_i |\vec{\rho}_i \cdot \vec{E}|^2 = E_y[1 - \cos^2 \alpha \sin^2 \beta]
\]

This allows for retrieval of \(K(\beta)\), the fluorescence signal as a function of the projection of \(\vec{\rho}_1\) and \(\vec{\rho}_2\) onto the \(xy\) plane, by summing the peak fluorescence signatures from two orthogonal polarization images under equal excitation powers, \(\vec{E}\). The fluorescent signal from \(N\) \(NV^-\) centres is returned by the summation over all centres, following;

\[
K(\beta) = \sum_i^N [K_{xi} + K_{yi}] = \sum_i^N \vec{E}(1 + \cos^2 \beta_i)
\]
Figure 5: (a) Scattered amplitude image of 10\textit{nm} \pm 2\textit{nm} diamond nanoparticles excited under 532 \textit{nm} at 350 \textit{pW} with (c) simultaneous detection of fluorescent signal. (b) Scattering maxima are locally grouped using the characteristic cloverleaf scattering signature to enable automated colocalisation with fluorescent signatures so only fluorescent signatures with a corresponding scattering signal are considered. (d) A histogram of fluorescent counts, $K(\beta)$, as calculated for each scattering particle by the summation of two orthogonal polarization signals.
The absence of a fluorescent signal for the right-most particle as well as an absence in the $K_x$ image (not shown) is attributed to the presence of a ND without an $NV^-$ centre, allowing the ratio of fluorescence signal between particles with and without $NV^-$ centres to be determined.

The histogram of fluorescent counts, $K(\beta)$, calculated following equation 5 is presented for all located scattering objects in figure 5(d). Where no fluorescent signature can be located from a scattering object, the local fluorescent background is averaged for a $0.4\mu m^2$ area centred at the scatterer’s location in the fluorescent image; symbolically represented by averaging over the orange dashed box in figure 5(c). In this way, uncolocalised scattering objects effectively report on the average background fluorescent count rate of the sample. The peak located at $K(\beta) = 1400 cts/px$ corresponds to the average fluorescent background rate of the sample, where no fluorescent signature is located. The peak at $K(\beta) = 1700 cts/px$ represents scattering signals that colocalise well with a defined fluorescent signal, which we assign tentatively to the presence of a single $NV^-$ centre based on the manufacturers specifications ($1 - 2NV^-$ centres per ND) and a discrete increase above the background fluorescence rate. However, it is worth noting that an ND containing two unfavourably aligned $NV^-$ centres may also produce a similar signal level, though this population is expected to be small. Our approach could be extended to prove that these are indeed single $NV^-$ centres by adding a second APD and time-correlated single photon counting module to enable a Hanbury Brown-Twiss (or antibunching) measurement. The collected fluorescence distribution can be understood from equation 5, there is an expected spread in the primary peak from variations in the $\beta$ projection of the $NV^-$ centre and a tail to higher count rates likely resulting from the presence of multiple $NV^-$ centres. Out of 408 particles analysed, we find that 266 (65.12%) localise well with a fluorescent signal, a ratio the producer does not yet supply.
In conclusion, we have demonstrated an all optical method to simultaneously resolve the scattering features of 10\( \text{nm} \pm 2\text{nm} \) NDs and colocalise those with fluorescent signatures of \( NV^- \) centres. We observed good sensitivity even at low excitation powers (25 \( \mu \text{W} \)) despite the traditional limitation of optical observation due to extremely small cross section of nanodiamond. Additionally, the dipole-like behaviour of \( NV^- \) centres was observed by excitation under orthogonal incident polarizations. The ability to verify the presence of colour centres in individual particles is essential in the pursuit of using nanodiamonds in applications from quantum technologies to biological labelling.
