Short Convergent Synthesis of the Mycolactone Core
Through Lithiation-Boration Homologations

Christopher A. Brown[a] and Varinder K. Aggarwal*[a]

Abstract: Using iterative lithiation-boration homologations, the mycolactone toxin core has been synthesised in 13 steps and 17% overall yield. The rapid build up of molecular complexity, high convergence and high stereoselectivity are noteworthy features of the synthesis.

The third most common Mycobacterium infection (after M. tuberculosis and M. leprae) is that of M. ulcerans, the pathogen responsible for the severe ulcerative skin disease, Buruli ulcer.[1] Endemic in tropical Africa, it infects over 5000 patients per annum with 48% of cases being aged under 15.[14,3] Transmission is thought to occur by an aquatic organism bite,[3] with initial manifestation occurring as a painless skin nodule. If diagnosed early, simple antibiotic chemotherapy is effective (80%),[4] however if untreated, propagation of the infection results in large skin lesions of necrotic tissue and bone loss which are only treatable through aggressive surgery, resulting in scarring and loss of limb function.[2,5] The serious morbidity due to the socio-economic burden of a young disabled workforce in rural communities[6,7] resulted in the World Health Organization identifying Buruli ulcer as one of seventeen neglected tropical diseases requiring research.[7]

M. ulcerans secretes a unique polyketide-derived virulence factor, an equilibrating mixture of mycolactones A and B, 1 (Scheme 1, 3:2 trans: cis) which inhibits the immune response and causes necrosis of the infected tissue.[14,15] Small and co-workers[16] successfully isolated milligram quantities of 1 allowing structure elucidation by NMR[17] and confirmation of mycolactones A/B as the causative toxin through studies in vivo.[18] A number of congeners (C-F) have since been isolated containing the common lactone 2, varying only by the appended acyl side chain.[19]

The absolute stereochemistry of firstly the lactone core 2[22] and then mycolactones A/B 1[13] was determined through total synthesis by Kishi and co-workers. Multiple synthetic studies have since followed including a 3rd generation (>700mg)[14] synthesis of core 2 by Kishi, in addition to other accomplished syntheses by the groups of Negishi,[15] Blanchard,[16] and Altmann.[17] These efforts have enabled further research into the pathogenesis of Buruli ulcer,[18] aid the invention of new/simpler diagnostic techniques[19] and allowed structural activity relationships of the core.[16,17,20] These SAR investigations have shown that while the northern fragment can be augmented, a complete side chain is critical for the potency of 1.[20a] The side chain of 1 has already been synthesized by the groups of Kishi,[21] Negishi[22] and Feringa/Minnnaard,[23] so we therefore focused our efforts towards the synthesis of the lactone core 2. We were particularly keen on applying our recently developed lithiation-boration methodology,[24] which is highly effective in not only controlling stereochemistry but also simultaneously creating C-C bonds. Whilst such methodology has already been applied to a number of targets,[25] including strategies involving iterative homologations for generating contiguous stereocenters,[26] mycolactone core 2 represents a considerably higher level of complexity. Herein we describe our success in applying our lithiation-boration methodology to a short convergent synthesis of this target molecule.

Our retrosynthetic analysis began with disconnection to the known intermediate 3 (Scheme 2).[12,15] We considered a lithiation-boration disconnection between C11-C12 as this would lead to high convergency. Both boronic ester 4 and carbamate 5 could themselves be obtained through consecutive

lithiation-borylation reactions of fragments 7 and 10. Indeed, through our iterative methodology there was the prospect of coupling boronic ester 7 with building block 6 followed by carbamate 5 in one pot to give the lactone precursor 3. Similarly carbamate 5 could be constructed in one pot from iterative coupling of boronic ester 10 and carbamates 9 and 6.

We began with the synthesis of boronic ester 10, which was achieved in three high yielding steps (Scheme 3). Copper-catalyzed formal hydroboration[27] of alkynol 11 with Bpin₂ in the presence of MeOH gave the desired vinyl boronate in 83% yield as a single regio- and stereoisomer. Subsequent carbamoylation of the alcohol gave carbamate 12 in 87% yield. Matteson one-carbon homologation with chloromethylthallium 13 (formed in situ with 12)[28] gave the desired allylic boronic ester 10 as a 99:1 mixture with 12. High conversion was achieved through the addition of precooled nBuLi[29] and using an excess of the dihalide with respect to the organolithium to limit competing addition of nBuLi to boronic ester 12 and thereby favour lithium-halogen exchange. In contrast to vinyl boronic ester 12, allylic boronic ester 10 was unstable to silica gel but was nevertheless obtained in high purity by simple filtration and evaporation.

With boronic ester 10 in hand, our key lithiation-borylation reactions were examined (Scheme 4). The boronate complex, formed from the addition of 10 into 6 (1.5 equiv.), underwent 1,2-metallate rearrangement in refluxing Et₂O to form 14 in 83% yield. NMR analysis of the derived Mosher’s ester indicated that the homologation occurred in 97:3 e.r. Subsequent reaction of 14 with 9 (1.3 equiv.) proceeded well, providing alcohol 15 after oxidation in 77%, >97:3 e.r and 94.6 dr. The diastereomeric ratio is consistent with reactions that are under full reagent control employing lithiated carbamates 6 and 9 with 97:3 e.r. Thus, carbamate 15 was formed in 63% yield from 12 in three steps. These three steps could also be carried out sequentially, without intermediate purification (‘one-pot’), on identical scale in an increased 81% yield without detriment to dr and further performed on an 8 mmol scale thereby delivering 3.0 g of 15, with 85% recovery of (+)-sparteine. The potentially reactive carbamate group remained intact allowing us to circumvent functional group manipulation and, after C5 silyl protection (82%), we obtained the desired carbamate 5 in 48% over 6 steps from alcohol 11.

The synthesis of boronic ester 4 started with preparation of 7 g of alkene 8 through a four-step known procedure in 74% yield and 96:4 dr (Scheme 5).[18,17a] Direct formation of allylic boronate 7 was investigated, employing methallyl boronic ester 17 and Hoveyda-Grubbs 2nd generation catalyst 19, which gave 7 in 62% yield but only as a 90:10 E:Z mixture of isomers. Olefin metathesis with vinylic boronic ester 18 has been reported to occur with much higher selectivity[30] and was therefore explored. We were pleased to find that subjecting alkene 8 and vinylic boronic ester 18 to the identical cross metathesis conditions, yielded 20 as a single geometric isomer (0.4 mmol scale, 68% yield). However, upon scale up we encountered two major problems: i) a dramatic reduction in conversion (10% after 14 h, 3.8 mmol scale), and; ii) the formation of 1,2-disubstituted alkene 21 (15%). The latter observation has been described previously,[31] possibly due to the transposition of boron from the internal to the terminal position of alkene 18 and subsequent metathesis with 8. As this product was only observed by GC-MS after extended reaction times (over 10 h), it was attributed to a transmuted catalyst of 19 causing the isomerisation of 18.[32] Therefore, it was imperative to increase conversion over a shorter reaction time to avoid catalyst degradation. Through running the reaction at higher concentration (1.0 M) and adding the catalyst portion-wise (5+5 mol%), we increased conversion to 45% and reduced the amount of 21 formed (5%). Finally, periodic degassing of the reaction every two hours removed the ethylene content of the solution and further pushed the equilibrium towards vinyl boronate 20, achieving a 60% yield on a 5.3 mmol scale over 10 hours with minimal formation of alkene 21 (<5%).

With our two key building blocks in hand, we examined our final iterative lithiation-borylation process. Matteson one-carbon homologation of 20 proceeded in near quantitative yield and homologation of 7 with lithiated carbamate 6 (1.5 equiv.) gave our required fragment 4 in 81% isolated yield. Oxidation and NMR analysis showed it to be 97:3 dr; consistent with the homologation of 6 with analogous allylic boronate 10. For the final step, lithiation of 5 in the presence of (-)-sparteine was required, but in explorative lithiation-deuteration experiments we isolated diene 22[32] in 10% yield, in addition to the required deuterated product (90%). This showed that 10% lithiation of 5 occurred at the allylic position followed by E₂ elimination of the carbamate. We therefore used an excess of carbamate 5 (1.5 equiv.) with respect to boronic ester 4 (1.0 equiv.), and the final homologation and subsequent oxidation gave known intermediate 3 in 82% yield and high E₂[33] with 950 mg prepared. With isolation and chromatographic purification of each intermediate, 3 was formed from 20 in 66% over three steps. Once again, these three steps could also be carried out sequentially, without intermediate purification (‘one-pot’), in an increased 86% yield. As a result,
significant amounts (>900 mg) of 3 was obtained over 8 steps from (R)-3-hydroxybutyrate in 38 % overall yield.

Completion of the synthesis followed literature precedent (Scheme 6).[12,15] Selective deprotection of the primary silyl ether with TBAF (85%), followed by a two-step TEMPO/Pinnick oxidation, yielded acid 23 in 81%. Lactonization of the 12-membered core proceeded efficiently under Yamaguchi conditions (81% yield), and subsequent global deprotection with HF/pyridine gave the mycolactone core 2 in 80%. In forming the lactone ring, minor diastereomers observed in the formation of 3 were separated completing the synthesis of lactone 2, which was identical in all respects to the literature, in a total of 13 steps and 17% overall yield.

In conclusion, the shortest synthesis of the mycolactone core to date has been completed both in terms of longest linear sequence (13 vs 14[14] steps) and total step count (17 vs 28[15] steps). Moreover if the sequenced iterative homologation is counted as one step, then the mycolactone core is achieved in only 10 steps. Although a scalable route has already been accomplished, our synthesis is able to rapidly deliver significant amounts (>100 mg) of highly enantio- and diastereoenriched mycolactone core through utilization of simple carbamate building blocks. Both in terms of step count and scale, the synthesis showcases the power of lithiation-borylation methodology for the efficient, and convergent synthesis of complex molecules.

COMMUNICATION

[29] Through submersion of the needle tip into the solution ensures low temperature addition of the organolithiation to the reaction mixture.

[31] The less stable Grubbs 2nd generation catalyst formed more of 21 (20% conversion) in the same reaction time, supporting this inference.

[32] Structure of diene, see Supporting Information for full characterisation.

[33] Accurate assessment of the dr associated with the final homologation was not possible because of the presence of minor diastereomers associated with epimers at C13, C5 and C6. However, based on previous homologations with primary carbamates (and supported by the $^{13}$C NMR), we expect that the dr of the final homologation reaction to be >95.5. See Supporting Information for full details.
Using iterative lithiation-borylation homologations, the mycolactone toxin core has been synthesised in 13 steps and 17% overall yield. The rapid build-up of molecular complexity, high convergence and high stereoselectivity are noteworthy features of the synthesis.
