ABSTRACT

We analyze new SCUBA-2 submillimeter and archival SPIRE far-infrared imaging of a z = 1.62 cluster, Cl 0218.3−0510, which lies in the UKIRT Infrared Deep Sky Survey/Ultra-Deep Survey field of the SCUBA-2 Cosmology Legacy Survey. Combining these tracers of obscured star-formation activity with the extensive photometric and spectroscopic information available for this field, we identify 31 far-infrared/submillimeter-detected probable cluster members with bolometric luminosities $\gtrsim 10^{12} L_\odot$ and show that by virtue of their dust content and activity, these represent some of the reddest and brightest galaxies in this structure. We exploit ALMA submillimeter continuum observations, which cover one of these sources, to confirm the identification of a SCUBA-2-detected ultraluminous star-forming galaxy in this structure. Integrating the total star-formation activity in the central region of the structure, we estimate that it is an order of magnitude higher (in a mass-normalized sense) than clusters at $z \sim 0.5$–1. However, we also find that the most active cluster members do not reside in the densest regions of the structure, which instead host a population of passive and massive, red galaxies. We suggest that while the passive and active galaxies have comparable near-infrared luminosities at $z \sim 1.6$, $M_H \sim -23$, the subsequent stronger fading of the more active galaxies means that they will evolve into passive systems at the present day that are less luminous than the descendants of those galaxies that were already passive at $z \sim 1.6$ ($M_H \sim -20.5$ and $M_H \sim -21.5$, respectively, at $z \sim 0$). We conclude that the massive galaxy population in the dense cores of present-day clusters were already in place at $z = 1.6$ and that in Cl 0218.3−0510 we are seeing continuing infall of less extreme, but still ultraluminous, star-forming galaxies onto a pre-existing structure.

Key words: cosmology: observations – galaxies: clusters: individual (CI0218.3−0510) – galaxies: evolution – galaxies: formation

1. INTRODUCTION

Luminous ellipticals in the central regions of rich clusters are the most massive galaxies ($\gtrsim 10^{11} M_\odot$) at the present day. The stars in these galaxies are metal-rich, old, and surprisingly uniform: spectral analysis of typical $L^*$ ellipticals indicates luminosity-weighted ages of $\sim 8$–11 Gyr and hints that those at larger radii in clusters may be slightly younger (e.g., Nelan et al. 2005; Smith et al. 2012). This homogeneity in their stellar populations means that these galaxies show a “red sequence”—a tight correlation between luminosity and color that can be traced in clusters out to high redshifts (e.g., Ellis et al. 1997). The existence of a red sequence of passive galaxies in a cluster signals that most of these galaxies were formed at least $\sim 1$–$2$ Gyr prior to the epoch at which the cluster is observed, although the presence of dust-reddened, star-forming galaxies can confuse this interpretation.

Red galaxy sequences have been used to identify rare, massive clusters out to $z \sim 1.5$ (e.g., Gladders & Yee 2005; Papovich et al. 2010; Demarco et al. 2010; Muzzin et al. 2013). However, in most clusters at $z > 1$, they are sparsely populated (especially at fainter luminosities; e.g., Blakeslee et al. 2003). This suggests that $z \sim 1$ is the epoch where galaxies in high-density environments were evolving onto these passive sequences. The striking decline in the galaxy population on the passive red sequence at $z > 1$ implies a corresponding increase in the population of massive, star-forming galaxies in clusters at these epochs. Moreover, the metal-rich stars in local ellipticals
suggest that this early phase of star formation is dust enshrouded and so best identified in the mid-/far-infrared.

Building upon early mid-infrared studies with *Infrared Space Observatory* (e.g., Coia et al. 2005), the MIPS instrument onboard *Spitzer* allowed the first deep, truly panoramic mid-infrared searches for obscured starburst activity in distant clusters (e.g., Geach et al. 2006; Fadda et al. 2008; Haines et al. 2009; Biviano et al. 2011). These studies found an increasing frequency of mid-infrared starbursts on the outskirts of clusters out to \( z \sim 0.5 \). This is believed to represent the continued infall of star-forming galaxies into the clusters and their transformation into passive spheroids. Surveys of higher-redshift clusters trace the continuing increase in the star formation in clusters to at least \( z \sim 1 \) (Bai et al. 2007; Saintonge et al. 2008; Finn et al. 2010; Koyama et al. 2010; Webb et al. 2013) and potentially beyond (e.g., Koyama et al. 2013; Kubo et al. 2013).

Beyond \( z \sim 1 \), the mid-infrared provides an increasingly unreliable estimate of total star formation in the most obscured systems (e.g., Calzetti et al. 2006; Hainline et al. 2009) and so we instead need to employ far-infrared and submillimeter (submm) tracers. Small-area submm surveys of the cores of massive clusters at \( z \sim 0.2–0.5 \) have confirmed that, apart from activity associated with a few central cluster galaxies (Edge et al. 1999), these regions are indeed devoid of dusty, ultraluminous galaxies. However, submm surveys of the core regions of \( z > 0.5–1 \) clusters have uncovered a population of ultraluminous infrared galaxies (ULIRGs) in these environments (Best 2002; Webb et al. 2005; Noble et al. 2012). These surveys used SCUBA to map \( \sim 2''\)-diameter (\( \sim 1 \) Mpc) fields in the cores of around a dozen clusters at \( z \sim 1 \) and found a substantial number of ultraluminous starburst galaxies. The resulting 850 \( \mu \)m counts in these regions exceed the field by \( \sim 3–4 \times \) (Best 2002; Noble et al. 2012), suggesting that obscured starburst activity is increasingly common in cluster cores at \( z \sim 1 \). Indeed, the *Herschel* satellite has expanded the number of sensitive far-infrared surveys for ULIRGs in distant clusters, strengthening the evidence for a continued rise out to at least \( z \sim 1 \), with a few rare examples at \( z \sim 1.4–1.6 \) (Popesso et al. 2012; Santos et al. 2013; Pinto-Castro et al. 2013; Alberts et al. 2014).

With the SPIRE instrument (Griffin et al. 2010) on *Herschel* and the new SCUBA-2 camera (Holland et al. 2013) on the JCMT, we can significantly improve our understanding of ultraluminous activity in the most distant clusters. These instruments allow sensitive far-infrared/submm surveys over the wide areas necessary to determine if there is a continued increase in the starburst population outside cluster cores (as seen in the mid-infrared studies at lower redshift). We have therefore exploited new deep submm and far-infrared imaging from SCUBA-2 and SPIRE of the field around the cluster Cl 0218.3–0510 at \( z = 1.62 \) to investigate the active galaxy populations in this region.

Cl 0218.3–0510 was first identified through both an overdensity of red galaxies in the *SWIRE* survey’s *Spitzer* IRAC imaging of the UKIRT Infrared Deep Sky Survey (UKIDSS) Ultra-Deep Survey (UDS) field and as a potentially distant X-ray source in *XMM-Newton* imaging (Papovich et al. 2010; Finoguenov et al. 2010; Tanaka et al. 2010). It has been extensively studied (Pierre et al. 2012; Rudnick et al. 2012; Papovich et al. 2012; Tadaki et al. 2012); most notably, Tran et al. (2010) used 24 \( \mu \)m imaging from *Spitzer* MIPS to identify an apparent increase in the star-forming fraction in the highest density environments, the reverse of what is universally seen in clusters at lower redshifts. However, the interpretation in terms of star formation of the mid-infrared emission from galaxies in this \( z \sim 1.62 \) structure is particularly difficult as the MIPS 24 \( \mu \)m filter samples not only the redshifted polycyclic aromatic hydrocarbon (PAH) feature at 7.7 \( \mu \)m, which is expected to trace star formation, but also the 9.7 \( \mu \)m silicate absorption feature that is strong in obscured active galactic nuclei (AGNs) or particularly dense starbursts. The goal of this work is therefore to build upon these earlier studies by undertaking a survey of the far-infrared and submm emission from luminous star-forming galaxies within the cluster and its surroundings and so investigate the evolutionary state of the galaxy populations in this structure.

We note that two days before this paper was accepted, a similar analysis was presented by Santos et al. (2014), using similar SPIRE, MIPS, photometric and [O II] samples. The main differences between the two analyses are that we include SCUBA-2 in our far-infrared analysis, radio and MIPS catalogs in our deblending and an independent photometric redshift analysis. Santos et al. come to broadly similar conclusions to those presented here.

In Section 2, we describe the new and archival observations used in our analysis. In Section 3, we present our analysis and results, while in Section 4 we discuss these and give our main conclusions. In our analysis, we assume a cosmology with \( \Omega_m = 0.27, \Omega_{\Lambda} = 0.73, \) and \( H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1} \), giving an angular scale of 8.6 kpc arcsec\(^{-1} \) at \( z = 1.62 \) and an age of the universe at this redshift of 4.0 Gyr. All quoted magnitudes are in the AB system and errors on median values are derived from bootstrap resampling.

2. OBSERVATIONS, REDUCTION, AND ANALYSIS

Our analysis involves both SCUBA-2 850 \( \mu \)m observations and *Herschel* SPIRE maps at 250–500 \( \mu \)m to provide a census of the far-infrared/submm population in our survey area. To locate the counterparts to these sources (where the maps have relatively poor spatial resolution), we also use observations at higher spatial resolution in the radio and mid-infrared from the Very Large Array (VLA) and *Spitzer*, respectively. Finally, to determine if these counterparts are probable members of the \( z = 1.62 \) structure in this field, we use redshift information from spectroscopic and photometric redshifts, as well as narrowband imaging of this field. We now describe each of these elements of the analysis.

2.1. SCUBA-2

As part of the SCUBA-2 Cosmology Legacy Survey (S2CLS), observations with SCUBA-2 were obtained in Band 2 and upper-Band 3 weather conditions (\( T_{225\text{GHz}} = 0.05–0.10 \)) between 2011 October and 2013 February. To date, these total 130 hours of on-sky integration. The field center for the S2CLS UDS observations is 02 17 49.2, −05 05 54 (J2000) to ensure maximum overlap with the existing UKIDSS/UDS coverage of this field (Lawrence et al. 2007). The S2CLS observations employ a 3300″-diameter *PONG* pattern to uniformly cover the full field.

The 195 individual 40 min 850 \( \mu \)m scans are reduced using the map maker from the *SMURF* package (Jenness et al. 2011; Chapin et al. 2013). This involves the raw data being first flat fielded using ramps bracketing every science observation and then scaling the data to units of pW. The dynamic iterative map maker assumes that the signal recorded by a bolometer is a linear combination of: (1) a common-mode signal dominated by atmospheric water and ambient thermal emission, (2) the
astronomical signal (attenuated by atmospheric extinction), and  
(3) a noise term, reflecting any additional signal not accounted  
for by (1) or (2). The map maker attempts to solve for these  
components, refining the model until convergence is met, an  
acceptable tolerance has been reached, or a fixed number of  
iterations has been exhausted. This yields time series signals  
for each bolometer that ought to comprise just the astronomical  
signal, corrected for extinction, plus noise.

Filtering of the time series is performed in the frequency do- 
main, with bandpass filters equivalent to angular scales of  \( \theta = 2'' \text{--} 120'' \). The reduction also includes the usual filtering steps of  
spike removal (>10\( \sigma \) deviations in a moving boxcar) and DC  
step corrections. The signal from each bolometer’s time series is  
then projected onto a map, using the scan pattern, with the con- 
tribution to a given pixel weighted according to its time-domain  
variance (which is also used to estimate the \( \chi^2 \) tolerance in the  
fit derived by the map maker). Throughout the iterative map-  
making process, bad bolometers (those significantly deviating  
from the model) are flagged and do not contribute to the final  
map. Maps from independent scans are coadded in an optimal  
stack using the variance of the data contributing to each pixel  
to weight spatially aligned pixels. The average exposure time  
per 4'' pixel in the central ∼0.9 deg diameter region is ∼1.5 ks.  
Finally, since we are interested in (generally faint) extragalac- 
tic point sources, we apply a beam-matched filter to improve  
point-source detectability, resulting in a map with a noise level  
of 1.9 mJy rms.

For calibration, we adopt the sky opacity relation for  
SCUBA-2 that has been obtained by fitting extinction models  
to hundreds of standard calibrators observed since the commis- 
sioning of SCUBA-2 (Dempsey et al. 2013). The flux calibration  
for SCUBA-2 data has been examined by analyzing all flux cal- 
biration observations since the summer of 2011 until the date of  
obervation. The derived beam-matched flux conversion factor  
(FCF) has been found to be reasonably stable over this period  
and the average FCFs agree (within error) with those derived  
from the subset of standard calibrators observed on the nights of  
the observations presented here. Therefore, we have adopted the  
canonical calibration of \( \text{FCF}_{500} = 537 \pm 26 \text{ Jy beam}^{-1} \text{ PW}^{-1} \)  
here. A correction of ∼10% is included in order to compensate  
for flux lost due to filtering in the blank-field map. This is  
estimated by inserting a bright Gaussian point source into the  
time stream of each observation to measure the response of the  
model source to filtering.

To identify the submm sources, we search the beam- 
convolved signal-to-noise ratio map for pixels above a threshold  
\( > \Sigma_{\text{thresh}} \). If a pixel is found, we record the peak-pixel sky  
coordinate, flux density, and noise and mask out a circular region  
equivalent to \( 1.5 \times \) the size of the 15'' beam at 850 \( \mu \text{m} \). We  
then reduce \( \Sigma_{\text{thresh}} \) by a small amount and repeat the search. The  
catalog limit, below which we no longer trust the reality of “de- 
tection,” is the signal-to-noise level at which the contamination  
rate due to false detections (expected from pure Gaussian noise)  
exceeds 5%, corresponding to a significance of \( \sigma \sim 3.75 \) (we  
confirm this using the simulations described next). We detect 97  
discrete point sources above this significance within the survey  
area used in this analysis (Figure 1).

The completeness of our catalog is estimated by injecting  
artificial point sources into a blank map with the same noise  
properties as our real map. To create this map, we apply a  
jackknife approach and randomly invert half of the individual  
time series before coaddition (e.g., Weiß et al. 2009). The  
recovery rate of \( 10^5 \) sources (inserted in groups of 10 with fluxes  
drawn from a uniform distribution) then gives the completeness  
function. These simulated maps also allow us to estimate the  
noise-dependent flux boosting that occurs for sources with true  
fluxes close to the noise limit of the map and so we can determine  
a statistical correction to de-boost the fluxes measured of sources  
in the real map; typically, this correction is \( B < 10\% \). Finally,  
the source detection algorithm is applied to each of the jackknife  
maps with no fake sources injected in order to evaluate the false  
positive rate, which we find to be 5%, in agreement with the  
false detection rate expected for a map of this size assuming  
fluctuations from pure Gaussian noise.

We also stack both the SCUBA-2 maps and the SPIRE  
maps described below to derive statistical measurements of the  
typical far-infrared/submm luminosities of the less active  
cluster populations. This stacking involves extracting thumbnail  
maps around each source to be stacked and then median  
combining these, before measuring the average source flux for  
the sample.

### 2.2. Radio and MIPS 24 \( \mu \text{m} \)

In our analysis, we are seeking to identify far-infrared/submm  
sources that are potential members of the \( z = 1.6 \) structure  
around Cl 0218.3--0510. The spatial resolution of the far-  
infrared/submm data is typically poor (15''--30'' FWHM) and  
some of these maps are also confused. Hence, to locate the  
sources of emission at these wavelengths, we need to use obser- 
vation with higher spatial resolution, but in wavebands where  
there is likely to be a correspondence with the far-infrared/  
submm emission. The most commonly employed proxy for this  
purpose are the radio and mid-infrared (e.g., Ivison et al.  
1998, 2004). We therefore use catalogs of sources detected at  
1.4 GHz with the VLA and at 24 \( \mu \text{m} \) using Spitzer.

UDS20 is a VLA 1.4 GHz survey of the UDS field and the  
reduction, analysis, and the full catalog of sources from the sur- 
vey are presented in V. Arumugam et al. (2013, in preparation).  
The observations comprise a mosaic of 14 pointings covering a  
total area of ∼1.3 deg\(^2\) centered on the UDS and build upon  
the earlier A-array observations of this field in Simpson et al.  
(2006). UDS20 employs 160 hr of integration with the VLA in  
A, B, and C–D configurations at 1.4 GHz, yielding an almost  
constant rms noise of ∼10 \( \mu \text{Jy} \) across the full field (<8 \( \mu \text{Jy} \)  
at the field center) and a beam size of 1.8 FWHM. There are  
∼5100 sources detected at >4\( \sigma \) significance within the UDS.

The UDS was also surveyed in the mid-infrared for the Spitzer  
Legacy Program SpUDS (PI: J. Dunlop). The SpUDS imaging  
covers the entire UDS survey area using both the IRAC (3.6,  
4.5, 5.8, and 8 \( \mu \text{m} \)) and MIPS (24 \( \mu \text{m} \)) cameras. Reduced maps  
and source catalogs released by SpUDS can be found online.\(^{17}\)  
The MIPS image has an effective 1\( \sigma \) depth of ∼8 \( \mu \text{Jy} \) and we  
use the SpUDS catalog based on this image in our search for  
counterparts to the far-infrared/submm sources in this field. The  
IRAC imaging from SpUDS is also an important addition in the  
derivation of photometric redshifts for sources in the UDS field  
(see Section 2.4).

### 2.3. SPIRE/Herschel

SPIRE 250, 350, and 500 \( \mu \text{m} \) observations of the UDS were  
taken as part of the Herschel Multi-tiered Extra-galactic Survey  
(HerMES) guaranteed time program (Oliver et al. 2012). The  
total exposure time for the UDS was 37.8 ks, broken into 5.4  
ks blocks. For each observation, we retrieved the Level 2 data  
17 http://irsa.ipac.caltech.edu/data/SPITZER/SpUDS/
Figure 1. Left: the spatial distribution of members and probable members of the structure associated with the $z = 1.6$ cluster Cl 0218.3–0510 in the UKIDSS/UDS field. The area shown corresponds to the region surveyed by Tadaki et al. (2012) using SuprimeCam on Subaru and a narrowband filter with a wavelength corresponding to redshifted [OII] at $z = 1.62$. Their photometrically selected [OII]-emitting cluster members are plotted and we also show the other active cluster populations, including MIPS and radio sources, the far-infrared-detected examples of this population, the SCUBA-2-detected subset of these, and the potential [OII] companions to five submm sources. We highlight the candidate SCUBA-2-detected source whose identification as a member has been confirmed by ALMA continuum observations (J. M. Simpson et al., in preparation). The background grayscale is the smoothed density distribution (smoothed with a Gaussian kernel with a FWHM of 1.7 Mpc) of all available from the Herschel European Space Agency archive and aligned and coadded the maps. The final combined maps reach 1σ noise levels of 2.3, 2.0, and 2.7 mJy at 250, 350, and 500 μm, respectively (see Oliver et al. 2012). To match the SPIRE maps to the astrometric reference frame of the radio map, we stacked the SPIRE maps at the VLA radio positions, centroiding the stacked emission and deriving shifts of $\Delta < 1.5''$, which we apply to each map.

These deep SPIRE maps have coarse beams and are heavily confused, hence to measure reliable far-infrared fluxes we need to deblend them. We employ catalogs of Spitzer 24 μm and 1.4 GHz VLA sources (detected at >5σ) and remove any sources within 15'' of each other as duplicates) to construct a master “prior” catalog to deblend the SPIRE maps. We use a Monte Carlo algorithm to deblend the maps and give a short description of this here (it is described in full in Swinbank et al. 2014), which also describes the extensive tests and simulations employed to confirm its reliability.18 We split the area up into smaller sub-areas for deblending and fit beams at the positions of sources from our prior catalog, optimizing their amplitudes to best match the map. To ensure that we do not “over-deblend” the longer wavelength maps (where the beam is larger), when deblending the 350 μm map, we only include sources from the prior catalog that are detected at >2σ at 250 μm as priors for the 350 μm deblending (and similarly, for the 500 μm map, we only include sources detected at >2σ at 350 μm). Appropriate errors and limits for non-detections are derived from simulations. Swinbank et al. (2014) describe the simulations and comparisons with published catalogs that are used to confirm the reliability of their analysis. For UDS, these indicate 3σ detection limits of 9.2, 10.6, and 12.2 mJy at 250, 350, and 500 μm, respectively (comparable to those derived from the XID deblending procedure employed by HerMES; see Roseboom et al. 2010).

2.4. Redshifts

To support our analysis, we have gathered redshift information for confirmed and probable members of the $z = 1.6$ structure from a number of sources.

2.4.1. Confirmed Members: [OII] Narrowband Imaging

Tadaki et al. (2012) studied the star-forming galaxy population in the $z = 1.6$ structure through their redshifted [OII] 3727 emission, as detected in narrowband imaging (NB973) with SuprimeCam/Subaru taken by Ota et al. (2010). The NB973 filter ($\lambda_c = 9755$ Å, $\Delta \lambda = 202$ Å FWHM, using the $z_R$ filter for continuum correction) covers [OII] line emission at $z = 1.590–1.644$. This corresponds to ~6000 km s$^{-1}$ in the rest-frame, which is sufficient to encompass the spectrscopically identified members (see the next section) without including galaxies at significantly different redshifts. The stacked NB973 image has a total integration time of 5.5 hr in 1'' seeing, reaching a 5σ limiting magnitude of 25.4 in a 2''0 diameter aperture and covers a total area of 830 arcmin$^2$, corresponding to a survey volume of 1.4 × 10$^5$ Mpc$^3$. More details of the data reduction and analysis can be found in Tadaki et al. (2012) and Ota et al. (2010).

We adopt the survey region from Tadaki et al. (2012), which is roughly centered on the peak of the $z = 1.6$ structure, to define the area used in our study (Figure 1). This allows us to compare the obscured star-forming population in the structure with their survey of the less-obscured population across a range in local galaxy density. We employ the Tadaki et al. catalog, but with a simple optical/near-infrared color selection applied to remove contamination, instead of the photometric redshifts used in Tadaki et al. (2012), to reduce possible biases against...
obscured sources. The resulting catalog has a total of 441 likely [O\(\text{II}\)]-emitters in the \(z = 1.6\) structure that we include in our analysis.

### 2.4.2. Confirmed Members: UDSz and Archival Spectroscopy

The UDS field has significant archival spectroscopy, including surveys specifically targeting the members of the \(z = 1.6\) cluster (Papovich et al. 2010; Tanaka et al. 2010), AGNs in the field (Pierre et al. 2012), and the general galaxy population (Simpson et al. 2012, and references therein). One significant element of the latter is the recently completed UDSz ESO Large Programme (PI: O. Almaini). UDSz obtained spectra for \(\sim 3500\) \(K\)-band selected sources across the full UDS field using the Very Large Telescope/VIMOS and FORS2 spectrographs. A description of the target selection, reduction, and analysis of UDSz is given in Bradshaw et al. (2013), with further details provided in O. Almaini et al. (in preparation).

For our analysis, we rely on a compilation of redshifts from UDSz, supplemented by a small number of unpublished redshifts (S. Chapman 2013, private communication) and the archival spectroscopy from Papovich et al. (2010), Tanaka et al. (2010), and Pierre et al. (2012).

### 2.4.3. Probable Members: UDS Photometric Redshifts

Finally, our analysis employs photometric redshifts for galaxies in the UDS to isolate possible cluster members. While much less precise than the redshift information provided from the samples described above, the photometric redshifts obviously benefit from their uniform coverage of the field, as well as from the relatively deeper limiting magnitude to which redshift information can be obtained.

The photometric redshifts used here are described in Hartley et al. (2013) (see also Lani et al. 2013 and Simpson et al. 2012). The photometric basis of these redshifts is the deep near-infrared imaging of the 0.8 deg\(^2\) from the UDS element of the UKIDSS (Lawrence et al. 2007) using WFCAM on UKIRT. The DR8 release was used, with imaging reaching median depths of \(J = 24.9, H = 24.2,\) and \(K = 24.6\) (5\(\sigma\), 2\(''\) apertures).\(^{19}\) These near-infrared images are supplemented by the IRAC mid-infrared observations from the SpUDS Spitzer Legacy Programme (see Section 2.2), as well as optical imaging covering the whole field with SuprimeCam on Subaru. The latter data were obtained by Furusawa et al. (2008) for the Subaru/XMM-Newton Deep Survey and comprise \(B, V, R, i',\) and \(z'\) data reaching 5\(\sigma\) limits (in 2\(''\) diameter aperture) of \(B = 27.6, V = 27.2, R = 27.0, i' = 27.0,\) and \(z' = 26.0.\) The full UDS was also imaged in the \(u\)-band with MegaCam on CFHT (O. Almaini et al., in preparation) to a 5\(\sigma\) depth of \(u' = 26.75.\) Together, these observations provide \(uBVRIi'z'JK\) photometry for \(K \leq 24.5\)-limited sample.

The photometric redshift estimates are based on EAZY (Brammer et al. 2008). This code was applied in a two-step process where an initial calibration of the redshifts was derived for a sample of \(\sim 2100\) galaxies with reliable spectroscopic redshifts (archival and from UDSz; see Section 2.4.2) and excluding AGNs, to determine zero-point offsets between the photometric system of UDS and that used for the templates employed in EAZY, deriving offsets of \(\leq 0.05\) mag in all filters, except for \(u'.\) The templates library used in the fitting consists of the standard EAZY templates, plus a slightly reddened version (\(A_V = 0.1\)) of the bluest star-forming template, employing the Pei (1992) parameterization of the Small Magellanic Cloud extinction law. Based on this calibration, they obtained a normalized median absolute deviation estimate of the dispersion of \(\sigma_{\text{MAAD}}(z_{\text{phot}} - z_{\text{spec}}/(1 + z_{\text{spec}})) = 0.031\) for the spectroscopic training set. More details of the analysis and testing of the photometric redshift catalog can be found in Hartley et al. (2013).

### 2.5. Matching

As stated above, for reasons of uniformity, we restrict our analysis to the region of the UDS covered by the Tadaki et al. (2012) narrowband [O\(\text{II}\)] survey: a \(0.45 \times 0.55\) deg patch demarcated by a rectangle with vertices \([34.250, -5.450]\) and \([34.800, -5.000]\); see Figure 1. This is roughly centered on the peak of the galaxy density in the \(z = 1.6\) structure (Figure 1) and also covers lower-density regions in the outskirts of this structure. Within this region from our input catalogs, there are 97, 850 \(\mu m\) sources, 402 1.4 GHz sources, 891 MIPS 24 \(\mu m\) sources, and 441 [O\(\text{II}\)] emitters.

To determine the membership of the structure, we define a spectroscopic range of \(z = 1.61–1.66,\) using the limits of the overdensity in the field in a redshift histogram of the available spectroscopy. With this definition of membership, there are 14 spectroscopic sources from UDSz in the structure (of which four have matches in the [O\(\text{II}\)] sample). The archival spectroscopy of this field yields another 17 (after removing two that are duplicated in UDSz); 10 of these have matches in the [O\(\text{II}\)] sample. Hence, in total, we have 31 spectroscopic members of the structure in our survey area, of which 14 are [O\(\text{II}\)] emitters.

We are forced to adopt a broader range in photometric redshift than that used for the spectroscopic sample (and hence also broader than the dispersion in redshift expected for virialized members of a cluster) due to the uncertainties in the photometric redshifts. This choice is a trade-off between minimizing the contamination by interlopers and maximizing the number of true cluster members selected. For the photometric redshift boundaries, we aim for a conservative cut (to reduce false matches) and so select \(z_{\text{det}} = 1.59–1.71.\) We find that 15/31 (48\%) of the UDSz/archival members have photometric redshifts in this range and, based on the average source densities across \(z = 1.3–2.0,\) we estimate potential contamination in our sample by interlopers of 40\%–60\% (Figure 1). Hence, the interloper fraction roughly balances the incompleteness due to the photometric redshift errors. This selection criterion results in 2793 photometric members of the structure from the UDS photometric catalog of Hartley et al. (2013) within our survey region. Of these, 207 are in the [O\(\text{II}\)] sample, 10 are in the archival spectroscopic sample, and 12 are in the UDSz spectroscopic sample. Thus, combining the spectroscopic, [O\(\text{II}\)], and photometric samples, there are 3031 members or probable members of the \(z = 1.6\) structure within our survey area.

As stated earlier, to circumvent the poor resolution of the submm catalogs of this region from SCUBA-2 and SPIRE, as is standard in this field, we make use of more precisely located proxies to identify likely sources for this emission: radio and MIPS sources (e.g., Biggs et al. 2011). These catalogs are exploited in different ways for SCUBA-2 and SPIRE. Due to its depth and the 850 \(\mu m\) source counts, the SCUBA-2 map is not confused and so we simply use the source catalog from these data and then associate detected sources with MIPS or radio counterparts using a probabilistic test, following Biggs et al. (2011). We adopt a definition of robust counterparts of a matching probability of \(P \leq 0.05\) and search for counterparts within a maximum 8\(''\) search radius (Ivison et al. 2007).
Based on recent ALMA observations of submm sources from similar-resolution data, we expect this probability cut to provide a relatively pure (>80% correct) but incomplete sample of identifications for the submm sources (Hodge et al. 2013). In contrast, the deeper SPIRE maps of the UDS field are confused and so we derive fluxes or limits on the emission using the deblended catalog described in Section 2.3. This process then results in far-infrared/submm fluxes or limits for the emission from each source in the combined radio and MIPS catalog.

To identify which sources are members of the z = 1.6 structure, we then match the MIPS and radio samples to the catalogs of confirmed or probable members ([O II], spectroscopic, and photometric redshifts) with search radii that reflect the uncertainty in the positions of sources (due to resolution and signal-to-noise issues) and the relative astrometric alignment of the different samples. We therefore match to the closest counterpart in the membership catalog within a 1" radius (which should yield <1% false-positive matches). We find 58 members or probable members that are either radio detected or have bright MIPS counterparts: 28 MIPS, 19 radio, and 11 MIPS and radio. Of these, one MIPS source has an archival spectroscopic redshift (it is an AGN), six sources are narrowband [O II]-emitters (one radio, five MIPS, of which two MIPS are also members based on their photometric redshifts), and the remaining 51 sources are members based on their photometric redshifts (33 MIPS detected, 29 radio, and 11 both MIPS and radio).

Of the 58 MIPS- or radio-selected members, 31 have detectable 250 μm emission in the SPIRE map and 22 are detected in two or more bands and so can have spectral energy distributions (SEDs) fitted; the details of these sources are given in Table 1. Five of these also match SCUBA-2 submm sources. By chance, one of these five SCUBA-2 sources (#373 in Table 1) was included in a high-priority Cycle 1 ALMA program to image the 30 bright submm sources from the S2CLS map of the UDS. These Band 7 (870 μm) continuum observations reach 1σ depths of ~0.2 mJy and confirm that the MIPS/radio source with a photometric redshift of zphot = 1.67 we had identified is indeed a bright submm galaxy (SMG; see Figure 1). This provides a useful test of the reliability of the identification process used in our analysis. Full details of the ALMA program are given in J. M. Simpson et al. (in preparation).

Finally, we have also stacked the emission in the SPIRE and SCUBA-2 maps from the individually undetected MIPS/radio cluster members and the [O II] narrowband sample.

20 An additional SCUBA-2 source matches a non-FIR-detected MIPS counterpart. Indeed, matching the SCUBA-2 sample directly to the [O II] narrowband emitter catalog, we find another five SCUBA-2 sources with apparent statistical associations, P ≤ 0.01, with [O II] emitters (one matching a close pair of [O II] emitters). However, the photometric properties of these emitters, blue colors and low luminosities, are characteristic of the bulk of the [O II] population, rather than the redder and more dusty submm sources (as shown by the MIPS/radio-identified examples; Figure 3). For this reason, we believe that these [O II]-submm associations are likely to indicate that the [O II] sources are companions to the true submm emitter and so we cannot use these to investigate the properties of that population. However, we find no evidence for an excess of red/luminous sources in the immediate vicinity of these five apparent [O II]-submm pairs, nor do they have obvious SPIRE counterparts, and so while they could represent cold, low-luminosity cluster members, we have chosen to discard them from our analysis.
The MIPS/radio sample are stacked on the original SPIRE maps, while for the [O\textsc{ii}] sample we have stacked these sources on the residual maps constructed by removing all of the de-blended sources (using a 5\sigma MIPS/radio-based prior catalog). These stacked fluxes yield detections in all three SPIRE bands for both samples, which are also reported in Table 1.

3. ANALYSIS AND RESULTS

We plot the spatial and redshift distributions of the various populations inhabiting the $z = 1.6$ cluster in Figure 1. The spatial distribution of cluster members shows two dense clumps, with weaker structures spread across the whole of our survey region. The scale of this structure is commensurate with that expected for the progenitor of a massive cluster of galaxies at the present day (e.g., Governato et al. 1998; Chiang et al. 2013). The photometric redshift distributions display modest peaks in both the photometric and far-infrared/submm-detected populations at the cluster redshift. To test the significance of the peak in the far-infrared-detected sample within the redshift window we use to define membership, $z = 1.59–1.71$, we perform 10\textsuperscript{5} Monte Carlo simulations perturbing all of the photometric redshifts by their estimated errors and determining how frequently the number of sources in this redshift range exceeds that observed. We find that the observed peak occurs less than \textless 1% of the time by random chance. In addition, we note that given the potential contamination of the photometric member sample, it is reassuring that a generally similar structure is also seen in the spatial distribution of [O\textsc{ii}]-emitters. However, in this regard we also note that the more active members of the structure: the far-infrared galaxies and SMGs as well as the MIPS and radio sources, are somewhat less concentrated and we discuss this in more detail in Section 3.3.

3.1. SEDs and Multi-wavelength Properties

Figures 2 and 3 illustrate the colors and luminosities of the different cluster populations. Figure 2 shows a true-color $V\,K\,4.5\,\mu m$ representation of 160 kpc regions around the 31 far-infrared/submm-detected cluster members. We see that the far-infrared/submm sources are typically bright with relatively red colors. Figure 2 also shows that around half of the far-infrared/submm sources have potential companions on projected scales of \textless 30–50 kpc, with the 24 \mu m emission from the system frequently offset in the direction of these companions. However, we see little correlation between $L_{bol}$ and the presence or separation of these companions.

Figure 3 shows the distribution of probable cluster members on the $(z' - H) - 4.5\,\mu m$ plane (this combination of filters corresponds to restframe $(U - V) - M_H$ at $z \sim 1.6$). This confirms the tendency for the far-infrared/submm sources to be brighter and redder than the typical cluster member: at any given color, the far-infrared/submm sources are some of the brightest members of the population. Moreover, the far-infrared/submm sources are preferentially associated with the brightest members of the cluster population, with the SCUBA-2-detected sources being among the most luminous cluster galaxies at restframe $H$ band. This figure also highlights three MIPS-detected sources that are luminous at restframe $H$ band, but relatively blue; these are likely to be AGN-dominated systems.

To see how our observations compare with theoretical expectations, we also plot in Figure 3 the predicted colors and luminosities of galaxies taken from the Millennium database (Springel et al. 2005), using the prescription for galaxy evolution from Font et al. (2008). This model is an adaptation of the Bower et al. (2006) galaxy formation recipe, including the influence of stripping on the extended gas halos of galaxies in high-density regions (groups and clusters). To match our survey,
we select all halos at $z = 1.6$ with masses within 10% of the observed mass of Cl0218.3−0510 (see Section 3.2) and then identify those galaxies with $M_H < -19$ that are members of these halos. We contour the number density of galaxies as a function of their $(U − V)$ color and restframe $H$-band absolute magnitude, from 5% of the peak density in increments of 10%. While the model successfully reproduces the colors of the bulk of the star-forming galaxies, it clearly underpredicts the number of the reddest and brightest galaxies, both passive and active.

(A color version of this figure is available in the online journal.)

Figure 3. Observed $(z' − H)$-4.5 μm distribution for the confirmed and probable cluster members identified by their different selection techniques (see Section 2.4). These observables roughly map to $(U − V)−M_H$ in the restframe at $z ∼ 1.6$. Most of the photometric members define a blue cloud, which is also seen in the [O III] emitters, with the remainder inhabiting a more luminous and redder clump at $(z' − H) > 1.5$. The far-infrared/submm-detected and the MIPS/radio sources are distributed very differently, with most of them having redder colors and brighter restframe $H$-band luminosities than the less-active populations. We also mark the six statistically associated [O III] counterparts to five of the SCUBA-2 sources, which have much bluer colors than the bulk of the SPIRE/SCUBA-2 counterparts and which we exclude from our analysis (see Section 2.5). Finally, we compare the distribution of galaxies to that predicted by the Millennium simulation (see Section 3.1) using the galaxy evolution model of Font et al. (2008), where the number density of sources in the theoretical model is shown as contours starting at 5% of the peak density and incremented by 10%. While the model successfully reproduces the colors of the bulk of the star-forming galaxies, it clearly underpredicts the number of the reddest and brightest galaxies, both passive and active.

In Figure 4, we show the far-infrared/submm SEDs for the 22 galaxies that are individually detected in two or more bands by SPIRE or SCUBA-2. We fit a modified blackbody spectrum with $β = 1.5$ to each source to derive the restframe dust temperature, $T_d$, and integrate the fit to derive the bolometric luminosity, $L_{bol}$, both assuming the source is at $z = 1.6$. We derive a median luminosity of this population of $L_{bol} = (1.7±0.3)×10^{12} L_⊙$ and a dust temperature of $T_d = 33.0±1.2$ K, with the five SCUBA-2-detected SPIRE sources being slightly more luminous, but cooler: $L_{bol} = (2.1±0.3)×10^{12} L_⊙$ and $T_d = 29±4$ K. Details of the fits to the 22 individual sources are given in Table 1. We note that there is no measurable correlation between $L_{bol}$ and 24 μm flux, meaning that the MIPS fluxes of these $z = 1.6$ ULIRGs cannot be used to reliably infer their far-infrared luminosities or star-formation rates (SFRs; cf. Tran et al. 2010). We also note that these modified blackbody fits are expected to give lower luminosities than fitting template SEDs to the data and so we have scaled down the template luminosities from the literature by a factor $1.25 ± 0.01$ (Swinbank et al. 2014) when comparing with our blackbody fits in Figure 5. Finally, we warn that interferometric studies of single-dish submm sources have shown that a significant fraction of these comprise blends of multiple, fainter sources (e.g., Wang et al. 2011; Barger et al. 2012; Hodge et al. 2013). If this same effect is present in our sample it, will influence those measurements where the multiple SMGs are not all detected in the mid-infrared/radio wavebands used in our prior catalog. This will affect the derived luminosities more than the temperatures, as the $T_d$-$L_{bol}$ relation means that any lower-redshift, lower-luminosity, and hence cooler components will have dust SEDs that peak in the observed frame at similar wavelengths to the more distant, more luminous, and thus warmer components.

We also show in Figure 4 the equivalent fits to the stacked far-infrared/submm emission from those MIPS/radio cluster members that are not individually detected in two or more bands and the stack of those galaxies from the narrowband [O III] emitter sample. As expected, these samples show lower bolometric luminosities than the individually detected sources. The MIPS/radio sources have $L_{bol} = 0.4_{−0.9}^{+0.6}×10^{12} L_⊙$ and $T_d = 33±6$ K and the [O III] emitters have $L_{bol} = 0.04_{−0.05}^{+0.07}×10^{12} L_⊙$ and $T_d = 29±5$ K.

In Figure 5, we take the distribution of dust temperatures and bolometric luminosities for the various cluster populations and compare these with the trends found in both the local universe and at higher redshifts. We plot the individually detected SPIRE/SCUBA-2 sources and the stacked results from the undetected MIPS/radio cluster members and the [O III] population. To compare with these, we overplot the temperature-luminosity trend derived for $z ∼ 0$ Herschel galaxies by Symeonidis et al. (2013), who also adopted $β = 1.5$, the selection limit as a function of dust temperature expected for a source with a constant 250 μm SPIRE flux at $z = 1.6$, which roughly defines the selection boundary for our sample and the distribution of $T_d$-$L_{bol}$ predicted for the local IRAS population after application of our 250 μm flux limit (Valiante et al. 2009; see also Chapin et al. 2009). We also plot the distribution of temperatures/luminosities derived for a sample of high-redshift, ALMA-detected SMGs from Swinbank et al. (2014). We see from these that the SPIRE- and SPIRE/SCUBA-2-detected cluster members have a similar range in luminosity and temperature to the field population at high redshift, with both populations having slightly cooler temperatures, $ΔT_d ∼ 5.3±1.6$ K than implied by an extrapolation to high luminosities of the low-redshift Herschel or IRAS temperature-luminosity trends. In contrast, the stacked SED fits for the less-active cluster populations are in good agreement with the low-redshift trend, suggesting a closer similarity in the dust properties between lower-luminosity sources at high and low redshift than is seen for the ultraluminous population.

3.2. Mass-normalized Integrated SFR

Figure 5 also shows the bolometric luminosity function for the various cluster populations from our direct detections and stacks. For this calculation, we have adopted a survey volume of $1.4×10^3$ Mpc$^3$ from Tadaki et al. (2012). This corresponds to a 50 Mpc cube and hence is likely to be an upper limit to the actual volume spanned by the photometrically defined cluster members (e.g., Chiang et al. 2013). As a result, we expect that our number densities will be underestimated, although this statement is complicated by the competing effects of incompleteness and...
Figure 4. Far-infrared/submm SEDs for the 22 cluster members with two or more detections in the SPIRE and SCUBA-2 wavebands (see also Table 1). We fit a modified blackbody model, with $\beta = 1.5$, to the SPIRE 250, 350, and 500 $\mu$m and SCUBA-2 850 $\mu$m data points (non-detections are plotted at a flux corresponding to $1\sigma$). The median luminosity and temperature of this sample is $L_{\text{bol}} = (1.7 \pm 0.3) \times 10^{12} L_\odot$ and $T_d = 33.0 \pm 1.2$ K. The best-fit models are shown by the solid curves and the $1\sigma$ limits are shown by dotted curves. In addition, we show in the lower right the equivalent fits to the stacked far-infrared/submm emission from those MIPS/radio cluster members that are not individually detected in more than one band and from the narrowband [O II] sample. As expected, these samples show lower bolometric luminosities than the individually detected sources with: MIPS/radio, $L_{\text{bol}} = 0.4_{-0.3}^{+0.5} \times 10^{12} L_\odot$ and $T_d = 33 \pm 6$ K; [O II], $L_{\text{IR}} = 0.04_{-0.03}^{+0.07} \times 10^{12} L_\odot$ and $T_d = 29 \pm 5$ K.

(A color version of this figure is available in the online journal.)
contamination in our sample (see Section 2.5). Nevertheless, as we use the same volume for all three cluster populations, this uncertainty should not strongly affect the relative number densities derived for the three subsamples.

As expected, Figure 5 shows that the progressively less-active cluster members have correspondingly higher number densities. For comparison, we also plot two high-redshift samples: a 250 μm-selected field sample from Casey et al. (2012) lying at similar redshifts to our cluster sample, z = 1.2–1.6, and the ALMA-identified z ~ 2 870 μm-selected sample from Swinbank et al. (2014). At the bright end, the luminosities and space densities of the individually far-infrared/submm-detected cluster spaces are comparable to those derived for similar luminosity field populations at z ~ 1.5, although the faint end is relatively flat (for this reason, the contrast of the cluster population against the field is greatest for the more luminous SPIRE/SCUBA-2 sources; Figure 1), while the median luminosities and number densities derived for the less-active cluster populations broadly follow the form of the z ~ 1.5 field population from Casey et al. (2012).

To investigate the overall level of star-formation activity in Cl 0218.3–0510 compared with other clusters, we show in Figure 6 the variation in the mass-normalized SFR in clusters as a function of redshift, compared to similarly derived far-infrared-detected samples from Popesso et al. (2012), see also Alberts et al. (2014). To determine the mass-normalized SFR for Cl 0218.3–0510, we use the same criteria as employed by Popesso et al. (2012) and integrate the total bolumetric emission in our sample from sources with luminosities above 10^{11} L⊙ and lying within 2 Mpc of the cluster center (see Figure 1), converting this to a SFR following Kennicutt (1998). We derive an integrated SFR, from the far-infrared/submm detected sources and MIPS/radio sources, of 650 ± 370 M⊙ yr⁻¹, where the uncertainty is dominated by the potential contamination from interlopers. We caution that this emission arises from just five sources within the 2 Mpc region and so there is significant uncertainty in the total: 80% is contributed by the two SPIRE-detected sources, 15% from a single MIPS/radio source (undetected in SPIRE), and 5% from two [O ii] emitters with inferred luminosities above 10^{11} L⊙. For the normalizing mass, we adopt the cluster mass estimate from Pierre et al. (2012) of 7.7 × 10^{13} M⊙. Combining these, we estimate a mass-normalized SFR within the central 2 Mpc of 800 ± 500 yr⁻¹ in units of 10^{-14} M⊙ yr⁻¹ and show this in Figure 6. As can be seen from Figure 6, Cl 0218.3–0510 lies at a higher redshift than any of the structures studied by Popesso et al. (2012) and also displays a higher mass-normalized SFR than any of their clusters (although close to the highest-redshift example from Popesso et al.). The cluster also lies somewhat above the predicted evolutionary trend from Popesso et al. (2012), with the observed trend being closer to (1 + z)^{3} (Cowie et al. 2004; Geach et al. 2006) and supports claims of an order-of-magnitude enhancement in the level of star formation activity in overdense regions at z ~ 1.5, compared with z ~ 0.5–1.

3.3. Environment and Galaxy Formation

As we saw from Figure 1, the projected distribution of the photometric members around Cl 0218.3–0510 shows significant structure on the sky, which is also seen in the distribution of narrowband [O ii] emitters from the survey of Tadaki et al. (2012). The good agreement between the distribution of [O ii]-emitting members, which should be relatively free from contamination by interlopers, and the photometric redshift sample suggests that the latter is a relatively clean tracer of the integrated galaxy density within the structure. Both samples indicate that the structure includes two dense peaks and a number of less...
dense clumps of galaxies. However, the spatial distribution of the more active cluster populations appears more uniform, with most of these sources residing in intermediate- or low-density environments.

To provide a more quantitative comparison of the environments of the different populations, we plot in Figure 7 the distribution of bolometric luminosity as a function of galaxy density for the different cluster members. For the narrowband [O II] population, we have scaled their $L_{\text{bol}}$ to agree with the stacked detection shown in Figure 4. We use the surface density of the photometric members, smoothed with a Gaussian kernel with a FWHM of 1.7 Mpc from Figure 1 to define the environment on the grounds that it is independent of the populations we wish to test (although we note that two of our subsamples do require photometric redshifts to assign their membership) and it provides a robust measure of the global environment of the sources. The alternative approach of determining the density using the $N_{\text{th}}$ nearest neighbor (e.g., Tran et al. 2010) will tend to provide a more local measure of the density and as a result is more sensitive to contamination from interlopers than the smoothed density field.

Figure 7 shows that the [O II] population extends to higher galaxy densities than the more active, far-infrared/submm population, as well as the remaining individually undetected MIPS/radio sources—with few of the most active galaxies lying in the highest density regions. Hence, comparing the mean environmental density of the [O II] emitters, we estimate a local density of $13.4 \pm 0.5$ galaxies Mpc$^{-2}$, versus $11.8 \pm 0.2$ Mpc$^{-2}$ for the combined sample of far-infrared/submm luminous galaxies. A Kolmogorov–Smirnov test indicates a 1.1% chance that the two samples are drawn from the same underlying population. This trend suggests that the highest density regions in this $z = 1.6$ structure are devoid of the most actively star-forming galaxies, which instead are found in intermediate density environments. To quantify the extent of this environment effect, if we fit a linear relation to the running mean of $L_{\text{bol}}$ for the star-forming populations with galaxy surface density, we find a factor of $\sim 3$ decline in characteristic $L_{\text{bol}}$ over a factor of two range in local galaxy density. We show the median density for the passive cluster galaxies plotted in Figure 8 (using the color selection of Papovich et al. 2012), where these galaxies have been given an arbitrary $L_{\text{bol}}$ value. It can be seen that the most active galaxies reside in a distinct environment from these passive systems. Finally, we overplot the expected variation in mean SFR in a matched population of galaxies in clusters at $z = 1.6$ from the Millennium database using the Font et al. (2008) prescription for galaxy formation (we show representative error bars on the trend). We see that the model shows no decline in mean SFR with environment in halos at this epoch, in contrast with the observations.

(A color version of this figure is available in the online journal.)
the selection limit of the [O\textsc{i}] narrowband survey of this field (Figure 7). We assume a \( \sim 50\% \) completeness in the selection of cluster members and so reduce the inferred number densities by a factor of two. Finally, we calculate the running mean of the SFR as a function of local galaxy density and plot this in Figure 7. The model provides a reasonable match to the measured galaxy densities and mean SFR (although, in common with most theoretical galaxy formation models, it struggles to match the most luminous star-forming systems). However, it shows no significant variation in mean SFR with environment, in contrast to the decline seen in the observations in the higher-density regions.

Tran et al. (2010) and Tadaki et al. (2012) have both studied the environmental trends in star-forming galaxies within Cl 0218.3–0510 and have drawn conclusions that appear at first sight to be at variance with our findings. Tadaki et al. found no evidence for a variation with environment in the typical SFR of star-forming galaxies identified in their [O\textsc{i}] narrowband survey. As can be seen from Figure 7, we see the same result using our estimates of environment, in that the SFRs for the typically low-luminosity [O\textsc{i}] population do not vary with environment, with the trend for lower average SFR being driven by the small number of individually more luminous far-infrared sources that are absent in the highest-density regions. We conclude therefore that the results of Tadaki et al. and our results are consistent and point to an increasing environmental sensitivity in galaxies with higher SFRs.

Turning to the Tran et al. (2010) study, this used MIPS 24 \( \mu \)m observations of 17 sources from a sample of \( \sim 100 \) photometric and spectroscopically identified members in the central regions of the cluster to infer an increase in the fraction of strongly star-forming galaxies with increasing local density. This is in the opposite sense to the trend we see and we attribute this to one of three potential causes. First, our catalog of far-infrared/submm sources (drawn from a 30 \( \times \) larger area than that analyzed by Tran et al.) could either suffer significant contamination from non-members, which would appear predominantly in the lower-density regions, or the incompleteness in our selection could mean we are missing far-infrared/submm bright members in the higher-density regions. Both of these effects would reduce/remove any trend of increasing activity in higher-density regions. However, we discount the latter as there are few candidate far-infrared/submm sources at any redshift seen in projection within the higher-density regions. This leaves dilution due to contamination as a potential source of the disagreement, although we note that this would imply a much lower level of far-infrared/submm activity in this structure than suggested by either the trend in Figure 6 or the visibility of the structure in the redshift distribution of far-infrared/submm sources in Figure 1. Hence, we next consider the other two explanations, the first of which arises from the fact that Tran et al.’s study relies on 24 \( \mu \)m luminosity (restframe 9 \( \mu \)m) to infer SFRs. As we have discussed earlier, this is an uncertain assumption at \( z \sim 1.6 \) owing to the mix of continuum, PAH emission, and silicate absorption included in the MIPS passband and indeed we see no correlation at all between 24 \( \mu \)m flux and far-infrared luminosity for the sources in our sample. Hence, the trend observed by Tran et al. could have its origin in variations in either SFR, AGN contribution, or hot/cold dust luminosity ratio with environment (e.g., Rawle et al. 2012). In addition, Tran et al. used the 10th nearest neighbor in their sample to determine the galaxy density in their analysis; this provides a more local estimate of environment (on \( \sim 100 \) kpc scales in the densest regions) than our use of the density field of photometrically selected members smoothed on 1.6 Mpc scales and it is also more sensitive to contamination by interlopers in the galaxy sample. Nevertheless, if we adopt their approach, we find that some of the far-infrared/submm sources appear to reside in

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure8}
\caption{Left: the observed IRAC 4.5 \( \mu \)m magnitude distribution for the various cluster populations within the central 4 Mpc diameter region of the cluster: SPIRE/SCUBA-2 detected, narrowband [O\textsc{i}], and photometric redshift selected. We also plot in gray the distribution of passive cluster galaxies from Poggianti et al. (2013). The fading of the two populations is predicted to be \( \Delta M_\text{H} \sim 3.3 \) for the SPIRE/SCUBA-2 sources assuming they are seen halfway through a 100 Myr burst at \( z \sim 1.62 \) and \( \Delta M_{\text{submm}} \sim 1.4 \) for the passive populations, adopting a formation epoch of \( z \geq 2.5 \) consistent with the bulk of the field. SMG population (Simpson et al. 2014). This means that the present-day luminosities of the passive population at \( z \sim 0 \) match those of the brighter half of the local ellipticals, while the \( z = 1.6 \) ULIRGs fade to become the fainter half of the elliptical population at \( z \sim 0 \). The reader should be aware that the relative normalization of the distributions is arbitrary. (A color version of this figure is available in the online journal.)
\end{figure}
denser environments, especially when using a smaller number of neighbors to assess the environment (e.g., 5th nearest). Thus, the behavior that Tran et al. see may be driven by small-scale density enhancements in the very local environment of the most active galaxies, rather than providing an indication of enhanced activity in higher-density environments when defined on a larger scale. Indeed, such small-scale associations of galaxies could be responsible for triggering the activity in the far-infrared/submm sources through interactions and mergers. We conclude that the discrepancy between our results and those in Tran et al. may have its origin in either the small size of their study, their reliance on restframe 9 μm luminosity to infer SFR, or their use of a local measure of environment, which is more sensitive to transient, small-scale clustering than our global measure.

4. DISCUSSION AND CONCLUSIONS

While we have seen that there is an enhanced level of star formation activity in the z = 1.6 cluster Cl 0218.3–0510, compared with clusters at lower redshifts, we can also test if that activity is occurring in the densest regions of the cluster (as claimed by Tran et al. 2010). Theoretical models suggest that phase space is conserved during the hierarchical collapse of structures, implying that the densest parts of the structure at high redshift will correspond to the densest regions in its descendant in the local universe. These regions are populated by some of the oldest and most massive elliptical galaxies (e.g., Smith et al. 2012) and if the ultraluminous activity we see at high redshift is similarly associated with the densest parts of the structures, this would be an indication that we are seeing the formation phase of the oldest elliptical galaxies within these systems.

As Figure 7 illustrates, in this z = 1.6 structure we actually see that the most active, ultraluminous star-forming galaxies inhabit lower-density environments, while a population of apparently passive galaxies has already been built up in the highest-density regions. But are these galaxies passive because they have exhausted their gas reservoirs or has this gas been removed by environmental processes operating in these high-density regions? The comparison with the Font et al. model in Figure 7 is informative in this regard. Their model supplements the standard hierarchical suppression of star formation in satellite galaxies in high-density regions (as they are no longer the central galaxy of a halo of cooling gas) with additional stripping of extended gas reservoirs in their halos (termed “strangulation”), but this is clearly not sufficient to suppress the predicted activity in these regions. This failure is evident in both the lack of any variation in mean SFR with environment in Figure 7 and through the relative absence of luminous, red galaxies in the model predictions shown in Figure 3. We therefore suggest that the lack of activity in the passive population we observe in the highest-density regions of Cl 0218.3–0510 is because these galaxies have exhausted their gas reservoirs, rather than because the gas has been removed via an externally driven environmental process. Other processes are thus needed to suppress the star formation in these galaxies, for example feedback from AGNs, as suggested for the passive red galaxy population in a z = 1.46 cluster by Hayashi et al. (2011), which could aid in the removal of their gas reservoirs. Overall, we propose that we are not seeing the initial phase of formation of cluster ellipticals in Cl 0218.3–0510, which must instead have occurred at an earlier epoch, as suggested by studies of z ≥ 2 protoclusters (e.g., Geach et al. 2005; Chapman et al. 2009).

While the theoretical galaxy evolution models may not reproduce the details of the galaxy populations in this high-redshift cluster, we can still use the Millennium simulation to indicate the likely present-day descendant of this z = 1.62 structure and so link our observations to local populations. We search the simulation for z = 0 halos that had masses of $M_{cl} \sim 7.7 \times 10^{13} M_{\odot}$ at $z = 1.6$ and derive a mean mass of these of $M_{cl} = (5 \pm 3) \times 10^{14} M_{\odot}$, where the error is the 1σ scatter. This indicates that the cluster mass will grow by a factor of ~6× on average between $z = 1.6$ and the present day. So, can we empirically relate the galaxy populations we see at $z = 1.6$ to those of similarly, massive clusters today?

We begin by investigating the relationship between the far-infrared/submm sources and the other cluster populations; we show in Figure 8 the 4.5 μm magnitude distributions for the different populations within a 4 Mpc diameter region centered on Cl 0218.3–0510 (Figure 1). As expected from Figure 3, the far-infrared/submm detected sources are brighter in the restframe $H$ band (median $H$ band absolute magnitude of $M_H = -23.6 \pm 0.6$) than the narrowband [O II] emitters or the photometric redshift sample (median $H$ band absolute magnitudes of $M_H = -21.6 \pm 1.1$ and $M_H = -21.2 \pm 1.2$, respectively). We also compare these distributions with the passive cluster population in the $z = 1.6$ structure, selected using the $zJ$ color criteria for passive galaxies from Papovich et al. (2012), which have $M_H = -22.9 \pm 0.3$. Interestingly, these passive galaxies have comparable restframe $H$-band luminosities to the far-infrared/submm population. However, the latter galaxies—which are currently in a very active phase—are expected to fade more than those galaxies that are already passive at $z = 1.6$ and so will correspond to intrinsically lower-luminosity galaxies at the present day, assuming that neither population undergoes a subsequent phase of significant star formation or merging.

To illustrate the possible subsequent evolution of these populations, we also show in Figure 8 a qualitative prediction for the relative absolute $H$-band magnitude distributions for the descendants of the SPIRE/SCUBA-2 and passive cluster members at $z \sim 0$. The fading of the far-infrared/submm sources is expected to be $\Delta M_H \sim 3.3$, assuming that they are seen halfway through a 100 Myr burst at $z = 1.6$ (this is the canonical duration of SMGs; e.g., Hickox et al. 2012). In contrast, the passive population at $z = 1.6$ will fade by only $\Delta M_H \sim 1.4$, adopting a formation epoch of $z \sim 2.5$ consistent with the bulk of the field SMG population (Simpson et al. 2014). Figure 8 compares these two faded populations with the observed absolute $H$-band magnitude distribution of a volume-limited survey of local elliptical galaxies with morphological classifications from Poggianti et al. (2013). We see that the effects of the differential fading of the ULIRGs and passive populations since $z = 1.6$ means that the passive galaxies are a good match for the luminosities of the brightest ~50% of elliptical galaxies at $z \sim 0$, while the ULIRG population from Cl 0218.3–0510 has faded further and these galaxies now match the fainter half of the distribution of ellipticals seen locally. Given the different spatial distributions of these two populations within Cl 0218.3–0510, we would also expect this difference in formation age to remain, with the more luminous ellipticals in the cores of massive clusters today being older than the somewhat less luminous systems further out (e.g., Smith et al. 2012).

The main conclusions of this work are:

1. We combined SCUBA-2 submm and Herschel far-infrared imaging of a ~0.25 deg² area containing the $z = 1.62$ cluster Cl 0218.3–0510. We use these data, in conjunction
with Spitzer mid-infrared and VLA radio observations and photometric and spectroscopic redshifts, to identify far-infrared/submm bright galaxies that are probable members of the structure around this high-redshift cluster. We show that ALMA Cycle 1 observations of one of the proposed identifications confirms that the submm emission arises from a MIPS/radio source with a photometric redshift of $z_{\text{phot}} = 1.67$.

2. We find that these far-infrared/submm-bright members have ULIRG-like luminosities and comprise some of the brightest and reddest cluster galaxies in the restframe optical/near-infrared. Their restframe near-infrared magnitudes are comparable to the brightest passive galaxies seen in the core regions of the $z = 1.6$ cluster, with $M_H \sim -23$.

3. We determine the dust temperature-luminosity relation for the various classes of active galaxies in the cluster, using modified blackbody fits to the individual far-infrared/submm-detected sources and fits to the stacked photometry of the less-active MIPS/radio sources and [O II] emitters. We find that the latter two samples of lower-luminosity sources, $L_{\text{bol}} \lesssim 10^{10} - 11 L_{\odot}$, lie on the local $T_d-L_{\text{bol}}$ relation, but that the far-infrared/submm-detected sources, with $L_{\text{bol}} \gtrsim 10^{12} L_{\odot}$, are some $\Delta T_d \sim 5.3 \pm 1.6$ K cooler on average than comparable luminosity galaxies at $z \sim 0$.

4. By integrating the total SFR in all galaxy populations with bolometric luminosities $\gtrsim 10^{11} L_{\odot}$, we derive a total mass-normalized SFR of $800 \pm 500$ yr$^{-1}$ (in units of $10^{-14} M_{\odot}$) within the central 2 Mpc. This mass-normalized SFR is an order of magnitude higher than seen in typical $z \sim 0.5$–1 clusters and indicates a continued increase in the star formation activity in clusters out to the earliest epochs probed.

5. Comparing the spatial distribution of the far-infrared/submm bright members with less active galaxy populations in the structure, we find that the most active galaxies are not found in the densest regions, which are instead traced by luminous galaxies with colors consistent with passive stellar populations at $z \sim 1.6$. This is consistent with a scenario where the activity we observe relates to infall of galaxies onto a pre-existing cluster core, which already contains a population of passive, but luminous galaxies. We show that a toy model for the subsequent evolution of the passive and active populations in CI 0218.3–0510 matches the $H$-band luminosity distribution of elliptical galaxies at the present day, with the most active galaxies at $z = 1.6$ corresponding to the formation phase of some of the fainter elliptical galaxies seen at $z \sim 0$. If correct, this places the earliest phase of the formation of (the most massive) cluster ellipticals at $z \gg 1.6$, possibly extending out to $z \sim 5$ (Simpson et al. 2014).
