ABSTRACT

OBJECTIVES
We investigated trends and regional variation in the rate of arthroscopic knee surgery performed in England from 1997-98 to 2016-17.

DESIGN
Cross-sectional study of the national hospital episode statistics (HES) for England.

METHODS
All hospital episodes for patients undergoing a knee arthroscopy between 1 April 1997 and 31 March 2017 were extracted from HES by procedure code. Age and sex standardised rates of surgery were calculated using Office for National Statistic (ONS) population data as the denominator. Trends in the rate of surgery were analysed by procedure both nationally and by Clinical Commissioning Group (CCG).

RESULTS
A total of 1,088,872 arthroscopic partial meniscectomies (APMs), 326,600 diagnostic arthroscopies, 308,618 knee washouts, and 252,885 chondroplasties were identified (1,759,467 hospital admissions; 1,447,142 patients). The rate of APM increased from a low of 51/100,000 population (95% CI 51 to 52) in 1997-98 to a peak at 149/100,000 (95% CI 148 to 150) in 2013-14; then, after 2014-15, rates declined to 120/100,000 (95% CI 119 to 121) in 2016-17. Rates of arthroscopic knee washout and diagnostic arthroscopy declined steadily from 50/100,000 (95% CI 49 to 50) and 47/100,000 (95% CI 46 to 47) respectively in 1997-98, to 4.8/100,000 (95% CI 4.6 to 5.0) and 8.1/100,000 (95% CI 7.9 to 8.3) in 2016-17. Rates of chondroplasty have increased from a low of 3.2/100,000 (95% CI 3.0 to 3.3) in 1997-98 to 51/100,000 (95% CI 50.6 to 51.7) in 2016-17. Substantial regional and age-group variation in practice was detected. In 2016-17, between 11% (22/207) and 16% (34/207) of Clinical Commissioning Groups performed at least double the national average rate of each procedure.

CONCLUSIONS
Over the last twenty-years, and likely in response to new evidence, rates of arthroscopic knee washout and diagnostic arthroscopy have declined by up to 90%. APM rates increased about 130% overall, but have declined recently. Rates of chondroplasty increased about 15-fold. There is significant variation in practice but the appropriate population intervention rate for these procedures remains unknown.
What is already known on this topic?

- Knee arthroscopy is the most commonly performed orthopaedic surgical procedure worldwide and, internationally, there is considerable variation in the population intervention rate.
- Trial evidence has been published challenging the efficacy of arthroscopic debridement and washout for osteoarthritis and, more recently, arthroscopic partial meniscectomy.

What are the new findings?

- Although the rate of knee washout and arthroscopic partial meniscectomy has declined in response to published high-level evidence, there is large variation in practice.
- Arthroscopic chondroplasty surgery is being performed increasingly frequently with currently only limited supporting evidence.

How might it impact on clinical practice in the near future?

- The variation in intervention rates may drive more standardised clinical practice and the development of commissioning guidance.
- Measurement of the impact from improved treatment strategies on arthroscopic intervention rates and associated outcomes will be informed by comparison to the rates reported in this study.
INTRODUCTION

Of all musculoskeletal symptoms, knee pain is second only to back pain in terms of prevalence.[1] One quarter of all people over the age of 55 experience persistent episodes of knee pain and around one sixth of these people with knee pain consult their general practitioner each year.[2] The prevalence of painful disabling knee osteoarthritis in people aged over 55 years is 10%.[2] Meniscal pathology is also extremely common, with an overall prevalence of approximately 45% in patients over the age of 50 reporting knee pain, aching or stiffness.[3]

Historically, both osteoarthritis and meniscal pathology have been treated arthroscopically.[4] Knee arthroscopy is the most commonly performed type of orthopaedic surgical intervention, worldwide.[5,6] Over the last twenty years, a number of clinical trials have evaluated knee arthroscopy procedures, as summarised in Box 1 (see also Appendix 1). For example, between 1997 and 2008, multiple trials demonstrated the ineffectiveness of joint washout for the treatment of advanced osteoarthritis.[7–9] Some previous data suggests that rates of knee washout declined in response to this evidence.[10,11] Two recent trials have compared mechanical debridement with radiofrequency ‘chondroplasty’ for the treatment of articular cartilage damage.[12,13] The number of these procedures performed and the trends in practice are, however, unknown.

Meniscal tears may be managed surgically with either arthroscopic meniscal repair or excision (meniscectomy).[14,15] Trials published between 2007 and 2016 challenged the effectiveness of arthroscopic partial meniscectomy (APM) to treat meniscal tears in many patients groups.[16–23] This was concerning as arthroscopic knee surgery is not an entirely benign procedure and may be associated with rare but serious complications.[24,25] In England, simple procedure count data suggested a rapid rise in the rate of arthroscopic knee surgery until at least 2012.[24,26] However, all but one of the clinical trials evaluating APM was published since 2012 and the impact of this evidence on standardised rates of surgery in clinical practice is unknown. As a result, the current healthcare burden of this surgery is uncertain and, furthermore, an analysis of the geographic variation in the rate of surgery has not been performed. The knee arthroscopy intervention rate varies considerably between countries and regional variation in similar procedures, such as shoulder arthroscopy, has been reported previously.[27–32]

We aimed to determine the trend in the age and sex standardised population intervention rate of arthroscopic knee surgery over a twenty-year period from 1997 to 2017. Particular focus is given to the analysis of APM surgery, given the recently published evidence and because this is the most commonly performed procedure. Regional variation was explored by Clinical Commissioning Group (CCG).
METHODS

Hospital Episode Statistics (HES) data was obtained from NHS Digital (application DARS-NIC-68703). The HES data contains a record of all attendances for NHS hospitals in England.[33] The data is submitted by hospitals for payment for the services they provide and also intended for secondary use, including research. HES includes episodes of care delivered in treatment centres (including those in the independent sector) but funded by the NHS, episodes of care in England where patients are resident outside of England, and privately funded patients treated within NHS England hospitals. The information held in the HES database includes patient demographic and residence data, primary and secondary diagnoses, and all procedures undertaken.

All HES records between 1 April 1997 and 31 March 2017 were extracted for patients undergoing: (1) arthroscopic partial meniscectomy, (2) diagnostic arthroscopy, (3) arthroscopic washout, and (4) arthroscopic chondroplasty. Episodes were identified from the Classification of Surgical Operations and Procedures (OPCS-4) codes in the procedure fields within the HES data (see Appendix 2 for OPCS-4 code list).[34] Simultaneous procedures (ipsilateral or contralateral) were included.

To investigate geographic variation in practice, the Clinical Commissioning Group (CCG) responsible for the episode of treatment was identified. In England, CCGs were created as part of the Health and Social Care Act 2012 and replaced Primary Care Trusts in April 2013.[35] CCGs are the statutory bodies responsible for the planning and commissioning of all health care services for their local area. As of April 2017, there were 207 CCGs in England and each is responsible for an average population of approximately 250,000 (range 70,000 to 900,000).[35,36] Population data by age, gender and year within each CCG was obtained from the Office for National Statistics (ONS) and linked with the HES data for analysis.

Statistical analysis

Stata v15.1 (StataCorp, College Station, Texas, USA) was used to perform all analysis. Descriptive statistics were used to summarise the age and sex of patients undergoing each type of procedure. Population data from the ONS was used to calculate age and sex standardised rates of intervention by year of treatment, following the methodology of the Association of Public Health Observatories (APHO).[37] Annual trends were reported at procedure level (not mutually exclusive: including simultaneous ipsilateral or contralateral procedures). Overall trends in the number of hospital care episodes (patient admissions) were determined. In accordance with ONS and NHS Digital guidance, rates where the number of events was less than six were suppressed.[38] The Geographic Information System, QGIS v2.99 (qgis.org), was used to graphically summarise age and sex standardised rates for each CCG, per year. Standardised CCG level data was determined for all episodes and mapped using the April 2017 boundaries for consistency over time.[39]
Patient and Public Involvement

The study was supported by a patient advisory group which provided input into a programme of research, including this study, prior to commencement.
RESULTS

Between 1 April 1997 and 31 March 2017, a total of 1,088,872 arthroscopic partial meniscectomies, 326,600 diagnostic knee arthroscopies, 308,618 washout procedures, and 252,885 chondroplasties were performed. This was a total of 1,976,975 procedures (1,759,467 hospital admissions) in 1,447,142 patients. A summary of the patient demographics for each procedure is shown in Table 1.

National trends

Figure 1 summarises the trends in the age-sex standardised rate of surgery per 100,000 population for each of type of arthroscopic procedure. Overall, the number of procedures increased 22% from 151/100,000 (95% confidence interval [CI] 150 to 152) in 1997-98 to 184/100,000 (95% CI 183 to 185) in 2016/17, and the number of hospital admissions for knee arthroscopy increased 9% from 137/100,000 (95% CI 135 to 138) to 149/100,000 (95% CI 148 to 150).

Arthroscopic partial meniscectomy (APM)

The rate of APM increased from a low of 51/100,000 population (95% CI 51 to 52) in 1997-98 to 92/100,000 (95% CI 91 to 93) in 2006-7, before increasing rapidly then plateauing between 2010 and 2015, with a peak at 149/100,000 (95% CI 148 to 150) in 2013-14 (Figure 1). Rates then declined to 120/100,000 (95% CI 119 to 121) in 2016-17. Figure 2 summarises the trend in the rate of APM surgery over time by age group. The greatest increase in the rate of surgery was seen in the 40-59 and 60-79 age groups between 1997-98 and 2013-14. This trend reversed after 2013-14 and a decline in the rate of APM in these age groups has been observed to 2016-17.

Arthroscopic knee washout, diagnostic arthroscopy

Rates of arthroscopic knee washout and diagnostic arthroscopy declined from 50/100,000 (95% CI 49 to 50) and 47/100,000 (95% CI 46 to 47) respectively in 1997-98, to 4.8/100,000 (95% CI 4.6 to 5.0) and 8.1/100,000 (95% CI 7.9 to 8.3) respectively in 2016-17 (Figure 1). Age-group trends are available in the supplementary appendix (Appendix 3).

Arthroscopic chondroplasty

Rates of chondroplasty increased steadily from a low of 3.2/100,000 (95% CI 3.0 to 3.3) in 1997-98 to 51/100,000 (95% CI 51 to 52) in 2016-17 (Figure 1). Age-group trends are available in the supplementary appendix (Appendix 3).
Variation by clinical commissioning group (CCG)

Geographic variation by CCG in the age-sex standardised rate of APM over time is summarised in Figure 3. There was a striking, near 10-fold, variation in the rate of surgery between CCGs for APM and all the other procedures evaluated (Figure 4; see also Appendix 3). In contrast to the overall declining national trend in APM, many CCGs performed surgery at an increasing rate or unchanged rate in recent years. Between 2015-16 and 2016-17, the rate of APM performed increased by at least 5% in twenty-five percent (52/207) of CCGs (Appendix 3).

In 2016-17, twenty-two CCGs (10.6%) performed more than double the national average rate of APM, whilst in the same year, fifteen CCGs (7.2%) performed less than 10% of the national average rate (Figure 4). For chondroplasty twelve CCGs (5.8%) performed less than 10% of the national average, whereas thirty CCGs (14.5%) performed at least double the national average rate. For washout/lavage sixty-two CCGs (30.0%) performed less than 10% of the national average, whereas thirty-two CCGs (15.5%) performed at least double the national average rate. For diagnostic arthroscopy, forty-two CCGs (20.3%) performed less than 10% of the national average, whereas thirty-four CCGs (16.4%) performed at least double the national average rate.
DISCUSSION

This study of over 1.7 million hospital episodes indicates that there has been a dramatic change in the practice of arthroscopic knee surgery over the last twenty years and, within these trends, there is considerable geographic variation in practice.

National trends

The rate of APM surgery increased by 190% from 51 per 100,000 in 1997-98 to 149 per 100,000 in 2013-14, before declining to 120 per 100,000 in 2016-17. In contrast, a consistent decline in the rate of arthroscopic washout procedures was observed – in line with published clinical trial evidence challenging the efficacy of arthroscopic washout and debridement for osteoarthritis between 1993 and 2008, and National Institute for Health and Care Excellence (NICE) guidance published in 2007 (Box 1).[7,8,40,41] A similar decline in the rate of diagnostic knee arthroscopy was noted over the twenty-year study period. This may reflect increased adoption of magnetic resonance imaging (MRI) as the diagnostic modality of choice for the knee.[42,43]

Rates of chondroplasty procedures including abrasion and radiofrequency chondroplasty have increased steadily by a total of 1500% from 3.2 per 100,000 in 1997-98 to 51 per 100,000 in 2016-17. NICE guidance issued in May 2014 was cautiously supportive of radiofrequency chondroplasty for discrete chondral defects of the knee, based on clinical trials comparing radiofrequency chondroplasty with mechanical debridement (Box 1).[13,44–46] The increase in the rate of chondroplasty has, however, occurred in the absence of high-quality controlled trials comparing the intervention to either a non-operative or placebo surgical comparator, or evaluating treatment in patients with non-discrete lesions. More evidence is required to determine the efficacy of this procedure and should be a priority for further research.

For APM, a large increase in the rate of surgery over time was noted in older age groups, 40-59 and 60-79, followed by a partial decline. Eight randomised controlled clinical trials of APM have been published between 2007 and 2016.[16–23] The decline was particularly evident since the publication of five of the eight trials in 2012-2013. These trials challenged the efficacy of the procedure, predominantly in older patients with degenerative knee disease; our study demonstrates some change in practice coincident with this evidence.

Variation by clinical commissioning group (CCG)

Although, there has been an overall decrease in the number of knee arthroscopy procedures performed in England in recent years, our findings show that there is considerable variation in this trend across CCGs. On average, 14% of CCGs were performing at least double the national average rate of these procedures in 2016-17. Factors underlying such regional variation have been previously investigated.[47] CCGs with
considerably higher rates of APM may have a greater number of specialist surgeons with greater belief in the efficacy of the procedure, greater availability of hospital resources such as appropriate day case theatre time, or the variation may reflect patient treatment choices – both regarding surgery versus alternative treatment options and also the ability of patients to choose their treating hospital.

Variation in knee arthroscopy intervention rates has been reported internationally. In the United States in 2006, a knee arthroscopy intervention rate of approximately 400 per 100,000 population was reported.[27] In 2012, the rate of knee arthroscopy in Scotland was around 120 per 100,000 in patients over the age of 60 and this rate remained relatively stable between 2000 and 2013.[28] To 2012, rates of arthroscopic meniscal surgery in Finland were approximately 125 per 100,000, yet the same study found the equivalent rate in Sweden was less than 50 per 100,000.[29] In Canada, a rate of approximately 180 per 100,000 was reported in 2004.[30] In Australia, a relatively stable rate of knee arthroscopy was reported from 2001 to 2008 at just under 350 per 100,000.[31] Comparison of data reported by studies from other countries is, however, limited by differing reporting years, variation in the procedures included and coding practices, and the inclusion or exclusion of patients treated in private hospitals.

Overall, in this study, the total number of procedures increased by 22% and the number of hospital episodes by 9% from 1997-98 to 2016-17. Perhaps the greatest challenge to the interpretation of these findings is that the ‘appropriate’ intervention rate for the population is unknown. For example, for APM, in response to the clinical trial evidence, several clinical guidelines have been produced.[26,48,49] The number of patients presenting annually meeting the clinical and radiological criteria representing surgical ‘candidacy’ according to these guidelines is, however, unknown. Further work is required in this area, considering the indications applied, patient preferences, an evaluation of risks, and an assessment of the associated rates of undesirable outcomes such as subsequent knee arthroplasty.

**Strengths and limitations**

This study has been performed using the most comprehensive and complete hospital episode dataset for England. All hospital episodes of NHS patients (including those treated in the independent sector) over a twenty-year period were included. The population intervention rates reported in this study will, however, be an underestimate of the true population rate as private patient data are not available unless these patients were treated in NHS hospitals. Although the proportion of arthroscopic procedures performed in the private sector over time is unknown, national data does indicate that private healthcare expenditure as a proportion of total healthcare expenditure has remained relatively stable.[50] For example, between 2005 and 2015, private expenditure increased just 1% from 17% of total expenditure to 18%. [50]
A further potential limitation is the reliance on accurate data coding. For this study, surgical procedure codes were analysed and the direct linkage of this data to hospital remuneration provides a strong incentive for hospitals to accurately record this information. It remains possible, however, that some of the apparent change in the number of procedures being performed may reflect a change in coding practice rather than a real change in practice. This is a potential limitation of all large health database studies, however given the importance of HES data records for reimbursement of hospital care costs and the anticipated impact from emerging clinical trial evidence and new guidelines issued, we believe a change in coding practice is unlikely to be the main cause of the trends observed.

Geographic variation data was available from 2002 and configured to the CCG boundaries as on 1st April 2017 for consistency over time. In interpreting these data, we note that CCGs only replaced the previous Primary Care Trusts in April 2013 and that not all CCG regions include a hospital that performs arthroscopic surgery. The regional rates of surgery are adjusted by the age and sex of the regional population, but patient migration and other geographic factors may underlie the reported variation. The purpose of this study was not, however, to determine the cause of variation but simply to report and discuss this variation and the associated trends in practice over time.

**Conclusion**

We believe the significant change in surgical practice likely represents a response, in part, to the publication of clinical trial evidence and guidelines, particularly applicable to the practice of knee washout and APM. There remains wide geographic variation in practice and the rate of arthroscopic chondroplasty has increased substantially without high-quality supporting evidence. For all types of arthroscopic knee surgery, the ‘appropriate’ population intervention rate that maximises the clinical and cost-effectiveness of these procedures is currently unknown and must be a priority for future research.
