Short title: cardiac magnetic resonance findings in survivors of out-of-hospital cardiac arrest

Word count (including title page, abstract, text, references, tables and figures legend): 5065

Conflicts of interest: none

ABSTRACT

Background: In patients who survived out-of-hospital cardiac arrest (OHCA) it is crucial to establish the underlying cause and its potential reversibility. **Objective:** We assessed the incremental diagnostic and prognostic role of early cardiac magnetic resonance (CMR) in survivors of OHCA. **Methods:** Among 139 consecutive OHCA patients, we enrolled 44 (median age 43 years; 84% males) patients who underwent coronary angiography and CMR ≤ 7 days after admission. The CMR protocol included T2-weighted sequences for myocardial edema and late gadolinium-enhancement (LGE) sequences for myocardial fibrosis. **Results:** Coronary angiography identified obstructive coronary artery disease (CAD) in 18/44 patients, in whom CMR confirmed the diagnosis of ischemic heart disease by demonstrating subendocardial or transmural LGE; the presence of myocardial edema allowed to differentiate between acute myocardial ischemia (N=12) and post-infarction myocardial scar (N=6). Among the remaining 26 patients without obstructive CAD, 19 (73%) showed at CMR dilated cardiomyopathy (N=5), myocarditis (N=4), mitral valve prolapse associated with LGE (N=3), ischemic scar (N=2), idiopathic non-ischemic scar (N=2), arrhythmogenic cardiomyopathy (N=1), hypertrophic cardiomyopathy (N=1) and Tako-Tsubo cardiomyopathy (N=1). In this subgroup, 6/26 (23%) had myocardial edema. During a mean follow-up of 36 ± 17 months, all 18 patients with myocardial edema had an uneventful outcome while 9/26 (35%) without myocardial edema experienced sudden arrhythmic death (N=1), appropriate defibrillator interventions (N=5) and non-arrhythmic death (N=3) ($p=0.006$). **Conclusions:** In survivors of OHCA, early CMR with a comprehensive tissue characterization protocol provided additional diagnostic and prognostic value. The identification of myocardial edema was associated with a favorable long-term outcome.

Key Words: cardiac arrest; cardiopulmonary resuscitation; cardiac blunt trauma; cardiac magnetic resonance; implantable cardioverter defibrillator; secondary prevention; ventricular arrhythmia.

INTRODUCTION

Out-of-hospital cardiac arrest (OHCA) due to ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT) can be caused by ischemic and non-ischemic heart diseases. In patients who suffered OHCA, clinical investigations aim at establishing what is the underlying disease and whether the cause of the arrhythmia is reversible. This is particularly relevant for decision to implant a defibrillator (ICD), that is not indicated in patients who experienced VT/VF due to a reversible myocardial injury like that secondary to myocardial ischemia of acute coronary syndromes or myocarditis[1-2]. In this context, the interpretation of standard investigations such as ECG, echocardiography and coronary angiography may not be straightforward and nonspecific findings secondary to the cardiac arrest and subsequent resuscitation may act as confounders[3-5].

Cardiac magnetic resonance (CMR), in addition to accurate assessment of ventricular function, allows the identification of myocardial tissue changes such as myocardial edema as evidenced by increased signal intensity on T2-weighted sequences and myocardial fibrosis by late gadolinium enhancement (LGE) on post-contrast sequences[6]. In the evaluation of patients who survived OHCA, the combination of sequences for myocardial edema and fibrosis has the potential to distinguish an acute and potentially reversible injury from a chronic and irreversible lesion[7].

The aim of the present study was to prospectively evaluate the incremental diagnostic and prognostic value of early (within one week after admission) CMR, enhanced with an accurate tissue characterization protocol including sequences for myocardial edema and fibrosis, in OHCA survivors.

METHODS

The study included all survivors of arrhythmic OHCA who were admitted to our institution during the study period 2011-2016 and underwent coronary angiography and CMR within one week of hospitalization. The CMR was performed in all patients who could be weaned from mechanical ventilation, had no neurological impairment and had no contraindications to CMR. The study complies with the Declaration of Helsinki, was approved by the Ethical Committee and all patients agreed to participate.

Coronary angiography

Coronary angiography was performed in all patients: at admission in those with ST-segment elevation at post-resuscitation ECG or in those with high clinical suspicious of ongoing myocardial ischemia; delayed in the others. A culprit coronary lesion was defined as obstructive ($\geq 70\%$) CAD with TIMI 0/1 flow with abrupt closure, or TIMI 2/3 flow with features suggestive of thrombus or ulcerated plaques, ST segment and T wave changes in the corresponding ECG location, and evidence of matching regional wall motion abnormality on left ventriculogram or echocardiogram[8].

Contrast-enhanced cardiac magnetic resonance

The CMR scan protocol systematically included steady-state free precession sequence (true FISP) cine images for morpho-functional evaluation, T2-weighted sequences for detection of myocardial edema and post-contrast sequences for detection of LGE. Details are reported in the supplemental file.

Follow-up

Patients were followed-up with serial outpatient evaluations or with telephonic interviews to determine the alive status and whether they reached the composite arrhythmic end-point including sudden death, cardiac arrest due to VF, sustained VT and appropriate ICD intervention. Sudden

94 death was defined as any natural death occurring instantaneously or within 60 minutes from
95 symptoms onset. Appropriate ICD intervention was defined as an ICD shock delivered in response
96 to a ventricular tachyarrhythmia >170 bpm and documented by stored intracardiac ECG data. All
97 ICD interventions were adjudicated as appropriate or inappropriate by two electrophysiologists
98 (AZ, DC) based on morphologic features, tachycardia onset, rate stability and atrial electrograms
99 (when available). ICD were programmed according to the MADIT-RIT trial high-rate or delayed-
100 therapy programming[9].

101

102 **Statistical Analysis**

103 Continuous and categorical variables are expressed as median (with 25th-75th %iles), and n
104 (%), respectively. Because of the small sample size, normality distribution was not assumed.
105 Categorical variables were compared by using the chi-square or Fisher exact test, as appropriate.
106 Continuous data were compared using the Mann-Whitney U test. A p-value of <0.05 was
107 considered statistically significant. Data were analysed with SPSS® version 23 (IBM®).

RESULTS

Among a consecutive series of 139 patients admitted for OHCA, 37 (27%) died during the acute phase. Among the remaining 102 patients, 58 (42%) were not recruited because of neurological impairment and/or mechanical ventilation (N=52), the presence of a no-MRI compatible pacemaker (N=4) or poor CMR quality images (N=2). Forty-four patients [median age 43 years (39-62 years); 84% males] met the enrollment criteria and constituted the definitive study cohort. (Table 1). Coronary angiography was performed at admission in 20 (45%) patients, including 7 (16%) with post-resuscitation ST-segment elevation, and within 4 days in the remaining patients.

Obstructive CAD

Angiographic evidence of obstructive coronary disease (≥ 1 coronary stenosis $\geq 70\%$) was found in 18 (41%) patients. A clear culprit coronary lesion was identified in 10 patients, 5/5 with single vessel disease and 5/13 with multiple vessels disease.

Cardiac magnetic resonance findings are summarized in Table 2.

The presence of myocardial edema at T2-weighted sequences consistent with an acute ischemic injury in 12/18 (67%) patients (Figure 1). In all cases, the regional distribution of myocardial edema was concordant with the territory which was tributary of a coronary artery with obstructive stenosis or occlusion. In 10 patients with an identifiable culprit coronary lesion, the regions of myocardial edema were always concordant with the regional distribution of the culprit coronary artery. Myocardial edema was present in 2 of the 8 patients with multiple vessels disease and no identifiable culprit coronary lesion. The Peak troponin I (normal value <0.017 ug/L) was significantly higher in patients with [12.2 ug/L (2.1-104.8)] compared with those without [2.8 ug/L (1.2-26.1)] LV myocardial edema ($p = 0.02$).

Left ventricular LGE with a subendocardial or transmural distribution was demonstrated in all patients (Figure 2). Among the 12 patients with myocardial edema, the regional distribution of LV

133 LGE corresponded to the edematous LV segments in 8 (consistent with an acute myocardial ischemic
134 injury without previous myocardial infarction) and extended to other non-edematous segments in 4
135 (consistent with an acute myocardial ischemic injury superimposed on a previous post-myocardial
136 infarction scar).

137 Right ventricular LGE was present in a patient with right ventricular myocardial infarction
138 due to occlusion of the proximal right coronary artery.

139

140 **No obstructive CAD**

141 Among the 26 (59%) patients with non-obstructive CAD, coronary angiography revealed
142 normal coronary arteries in 20 and non-obstructive coronary artery stenosis in 6. A negative history
143 of cardiac disease at risk of sudden cardiac death was documented in all but one patient with a
144 previous diagnosis of HCM. CMR allowed to identify a pathological myocardial substrate in 19
145 (73%) consistent with dilated cardiomyopathy (N=5); acute myocarditis (N=4, Figure 3), mitral valve
146 prolapse associated with LGE (N=3, Figure 4); ischemic heart disease (N=2), isolated non-ischemic
147 left ventricular scar (N=2, Figure 5), arrhythmogenic cardiomyopathy (N=1), hypertrophic
148 cardiomyopathy (N=1) and Tako-Tsubo cardiomyopathy (N=1) (Table 2).

149 Left ventricular myocardial edema was present in 6 (23%) patients. The following regional
150 distribution patterns of myocardial edema were identified: 1) midmyocardial or subepicardial pattern
151 involving the infero-lateral LV wall in 4 patients, consistent with a diagnosis of acute myocarditis
152 which was confirmed by endomyocardial biopsy in 3; 2) a subendocardial pattern in the mid-apical
153 antero-septal LV segments consistent with myocardial ischemia in one patient with a left anterior
154 descending artery stenosis that was judged as moderate at coronary angiography; 3) a transmural
155 pattern affecting circumferentially the mid-apical LV segments in one patient who received a
156 diagnosis of Tako-tsubo cardiomyopathy.

157 Left ventricular LGE was present in 18 (69%) patients, including 2 with ischemic distribution
158 (subendocardial or transmural) and 16 with a non-ischemic pattern (midmyocardial or subepicardial).
159 Non-ischemic myocardial fibrosis was found in isolation in 2 patients, and associated with other
160 cardiac diseases in the remaining 15 cases (i.e., cardiomyopathies, N=7; acute myocarditis, N=4; and
161 mitral valve prolapse, N=3).

162 Right ventricular LGE was present in two patients who fulfilled the International Task Force
163 diagnostic criteria for arrhythmogenic cardiomyopathy[10].
164

165 **Incremental diagnostic value of CMR**

166 In all 18 patients with obstructive CAD, tissue characterization by CMR confirmed the clinical
167 diagnosis of arrhythmic OHCA due to either acute coronary syndrome (N=12) or chronic ischemic
168 cardiac disease (post-infarction left ventricular scar with no evidence of acute myocardial edema)
169 (N=6).

170 Among the 26 OHCA survivors with no obstructive CAD, CMR modified the initial clinical
171 diagnosis in 11 (42%). Details are reported in Table 3 and Supplemental file.
172

173 **Clinical management**

174 An ICD was implanted in all patients with no evidence of acute ischemic injury (no LV
175 myocardial edema), but one who underwent surgical coronary revascularization and had a negative
176 electrophysiological study with programmed ventricular stimulation performed 12 days after surgery.
177 In addition, 5/12 OHCA survivors with evidence of acute myocardial infarction also received an ICD
178 because of severe reduction of LV ejection fraction after 40 days despite optimal medical therapy
179 (N=4) or moderate LV dysfunction in association with non-sustained VT and inducibility of sustained
180 VT at programmed ventricular stimulation (N=1).

181 Among the 26 OHCA survivors with no obstructive CAD, an ICD was implanted in 22. The
182 remaining 4 OCHA survivors did not receive an ICD for the following reasons: one with mitral valve
183 prolapse and severe mitral regurgitation underwent mitral valve repair and had a negative
184 electrophysiological study with programmed ventricular stimulation 15 days after surgery; one
185 patient with arrhythmogenic cardiomyopathy refused the device implantation; and in 2 patients with
186 acute myocarditis the ICD was deemed not indicated.

187

188 **Follow-up**

189 Overall, the mean follow-up period was 36 ± 17 months and no patients were lost to follow-up.
190 Five patients experienced appropriate ICD interventions and one patient, who refused ICD
191 implantation, died suddenly. The 6 patients with arrhythmic events during follow-up showed no
192 myocardial edema at CMR while all 18 patients who received a diagnosis of reversible myocardial
193 damage based on CMR evidence of acute myocardial ischemia (N=13), acute myocarditis (N=4) or
194 Tako-Tsubo cardiomyopathy (N=1), had an uneventful arrhythmic outcome. Five patients with
195 obstructive CAD had severe LV dysfunction at CE-CMR: of those, 3 died for non-arrhythmic causes
196 (refractory heart failure, acute myocardial infarction and abdominal aorta aneurysm rupture) and 1
197 experienced appropriate ICD intervention. The other 5 patients with arrhythmic events during follow-
198 up had a normal or mildly reduced LV function.

DISCUSSION

200 In survivors of OHCA the identification of the underlying arrhythmic myocardial substrate
201 has important implications for patients' management. Arrhythmic cardiac arrest may be the result of
202 different mechanisms and substrates which include: i) acute and transient electrical instability such
203 that occurring in the setting of acute myocardial ischemia or myocarditis, ii) rapid VT related to a
204 chronic myocardial scar resulting from a previous myocardial infarction or in the context of a
205 cardiomyopathy and iii) primarily electrical disease including genetically-determined ion channel
206 disease, drug toxicity or electrolyte imbalance in the absence of structural heart diseases. With regard
207 to the pathophysiological meaning of myocardial edema, it may either represent the bystander
208 hallmark of an acute cardiac injury (e.g. in acute myocardial infarction) or directly cause ventricular
209 arrhythmias by causing depolarization/repolarization inhomogeneity of myocardium [11].

210 According to current guidelines[1-2], ICD therapy for secondary prevention of sudden death
211 is reserved to patients with a stable myocardial substrate which exposes to persistent risk of VT/VF
212 relapses. On the contrary, ICD implantation is not justified in patients who suffered VT/VF due to
213 reversible causes, Interpretation of standard investigations such as ECG, echocardiography and
214 coronary angiography may not be straightforward to detect the cause of OHCA and structural
215 substrates of life-threatening ventricular arrhythmias may remain concealed[12-13]; in addition,
216 features of the so-called "post-resuscitation syndrome" may further confuse the clinical diagnosis[3-
217 5].

218 This study was designed to evaluate the diagnostic yield and prognostic implication of early
219 CMR study with a comprehensive protocol for tissue characterization, including T2-weighted
220 sequences for myocardial edema and post-gadolinium sequences for myocardial fibrosis in a cohort
221 of OHCA survivors with and without obstructive coronary artery disease at coronary angiography
222 who underwent CE-CMR within one week after the event. The main findings were the following: 1)

223 acute CMR study provided additional value for the identification of causes and mechanisms
224 responsible for arrhythmic OHCA; 2) the evaluation of the presence and regional distribution of both
225 myocardial edema and fibrosis allowed to differentiate acute and reversible myocardial lesions from
226 chronic and stable myocardial substrates, with significant implications on ICD therapy decision-
227 making; 3) identification of acute myocardial edema by CMR predicted an uneventful arrhythmic
228 outcome during follow-up; 4) in our population of OHCA survivors, we did not find any tissue
229 abnormalities at CMR suggestive of post-resuscitation myocardial contusion.

230 **Previous studies**

231 Previous studies showed that CMR provides incremental diagnostic value in patients who
232 survived an OHCA [14-17], but CMR scan protocols were often not uniform and performed late after
233 the acute event, thus reducing the sensitivity of T2-weighted sequences for myocardial edema.
234 Moreover, follow-up data to assess the prognostic value of comprehensive CMR tissue
235 characterization in OHCA are lacking. More details are reported in the supplemental file.

236 Our results confirm and extend previous observations on the diagnostic and prognostic value
237 of CMR in the setting of OHCA. In our study, the tissue characterization imaging protocol
238 incorporated systematic evaluation of both myocardial edema and LGE in order to distinguish acute
239 and potentially reversible myocardial injury from chronic and irreversible tissue damage[6-7]. At
240 variance with previous studies, all our patients underwent early CMR, i.e. within 7 days of
241 hospitalization, in order to provide the highest sensitivity for detection of transient myocardial edema
242 and were followed-up for a mean of 3 years to prospectively assess the prognostic value of CMR
243 findings.

244 **Diagnostic yield**

245 In patients with obstructive CAD, CMR confirmed the diagnosis of ischemic heart disease by
246 showing LGE with an ischemic distribution (subendocardial or transmural) in all cases. In addition,

247 T2-weighted sequences allowed to differentiate the arrhythmic substrate due to acute myocardial
248 ischemia, as suggested by the presence of myocardial edema in the territory tributary of a coronary
249 artery, from that of post-infarction myocardial scar[18]. The tissue characterization was also useful
250 for identification or confirmation of the culprit coronary artery, particularly in patients with multiple
251 vessels disease and equivocal coronary angiography findings.

252 In patients without obstructive CAD, CMR confirmed the clinical diagnosis in 58% of cases
253 and modified the clinical diagnosis in 42% by demonstrating previously unrecognized myocardial
254 substrates. Myocardial edema at T2-weighted sequences was present in 6 cases suggesting that the
255 OHCA was the result of an acute myocardial injury occurring in the setting of acute coronary
256 syndrome, myocarditis or Tako-tsubo cardiomyopathy. In the remaining patients without myocardial
257 edema, ventricular fibrillation was related to cardiomyopathies or recently identified substrates of
258 SCD such as the isolated non-ischemic myocardial scar [13] or the “arrhythmic” mitral valve prolapse
259 (i.e. floppy mitral valve associated with myocardial fibrosis that is localized at the base of the
260 papillary muscle or at the basal posterior wall behind the mitral leaflet) [19].

261 **Prognostic implications**

262 Although definite conclusions cannot be drawn because of the limited sample size, our study
263 results suggest that CMR may provide not only diagnostic but also prognostic information. Compared
264 with tissue characterization based on LGE alone, demonstration of myocardial edema by T2-weighted
265 CMR sequences was of additional value for establishing the acute and potentially reversible nature
266 of the arrhythmic myocardial substrate. These results have the potential to impact ICD decision
267 making because indications to device implantation depends on demonstration of chronic/non-
268 reversible myocardial lesion as the substrate underlying VT/VF[1-2]. In our study, patients with
269 myocardial edema suggesting an acute and potentially reversible myocardial lesion showed no
270 arrhythmic events over a mean follow-up of 3 years. By comparison, 23% of patients without

271 myocardial edema at CMR, who most likely had a chronic and non-reversible substrate, suffered
272 arrhythmic events during follow-up.

273 **Myocardial damage secondary to resuscitation**

274 The diagnostic accuracy of CMR has been definitely demonstrated in non-OHCA patients
275 and it is now applied in a variety of cardiac conditions. However, clinical interpretation of tissue
276 abnormalities in survivors of OHCA poses additional challenges because all patients received
277 cardiopulmonary resuscitation that may cause cardiac contusion. In our study we found no signs
278 suggestive of post-resuscitation myocardial contusions. Accordingly, myocardial edema at T2-
279 weighted sequences in patients with OHCA should be interpreted as the sign of an underlying
280 disease rather than a non-specific post-resuscitation injury. More details are reported in the
281 Supplemental File.

282 **Study limitations**

283 The main limitations of the study are that it was retrospective and conducted at a single
284 center. Moreover, our study reported on a relatively small number of patients and outcomes because
285 survivors of OHCA were rare and only a minority of them (32%) were eligible for early CMR.
286 Accordingly, our findings should be confirmed by further studies on larger populations and longer
287 follow-up before the use of early CMR for ICD-decision making in survivors of OHCA can be
288 clinically implemented.

289 In our study, the majority of patients were diagnosed with non-ischemic heart disease in
290 contrast with previous studies demonstrating that obstructive coronary artery disease is the most
291 common cause of OHCA [3]. This finding reflects the selection of patients because only OHCA
292 survivors who were able to undergo early CMR were included in the study. Therefore, the

293 distribution of OHCA substrates of our study sample cannot be considered representative of the
294 general population.

295 **Conclusions**

296 In survivors of OHCA, tissue characterization by early CMR was of significant diagnostic
297 and prognostic value in addition to standard clinical investigation (Supplemental figures 1 and 2).
298 Demonstration of myocardial edema by T2-weighted sequences, suggesting an acute and potentially
299 reversible myocardial injury, was associated with an uneventful arrhythmic follow-up. These
300 findings suggest that early CMR with T2-weighted sequences may be helpful to guide the decision
301 to implant an ICD for secondary prevention in survivors of OHCA that, according to current
302 guidelines, depends on the exclusion of possible transient and reversible causes for VT/VF such as
303 acute myocardial ischemia or acute myocarditis.

304

305 **Funding Sources:** the study was founded by the Target Projects RF-2013-02356762 grant of the
306 Italian Ministry of Health; the TRANSAC (translational arrhythmogenic cardiomyopathy) project,
307 2013, University of Padova, and the research grant BIRD (budget for integrated departmental
308 research) 2016, University of Padova, Italy.

370

371 **Figure 1. Out-of-hospital cardiac arrest in a patient with obstructive coronary artery disease.**

372 Out-of-hospital cardiac arrest occurring in a 64-year-old male with acute coronary syndrome.
373 Coronary angiography showing multiple vessels obstructive ($\geq 70\%$) coronary artery stenosis (arrows)
374 affecting both the right (A) and the left (B) coronary artery. Cardiac magnetic resonance showing
375 transmural myocardial edema (three chambers, long axis view; T2-weighted sequences) (C) and
376 subendocardial late gadolinium enhancement (three chamber, long axis view; T1-weighted inversion
377 recovery post-contrast sequences) (D) affecting the infero-lateral left ventricular wall which is
378 tributary of the left circumflex coronary artery.

379

380 **Figure 2. Out-of-hospital cardiac arrest in a patient with obstructive coronary artery disease.**

381 Out-of-hospital cardiac arrest occurring in a 57-year-old male with post-myocardial infarction scar.
382 Coronary angiography showing multiple vessels obstructive ($\geq 70\%$) coronary artery stenosis
383 (arrows) affecting both the right (A) and the left (B) coronary artery. Cardiac magnetic resonance
384 showing no myocardial edema (three chambers, long axis view; T2-weighted sequences) (C) and
385 transmural late gadolinium enhancement (three chambers, long axis view; T1-weighted inversion
386 recovery post-contrast sequences) (D) affecting the entire left ventricular lateral wall which is
387 tributary of the left circumflex coronary artery.

388

389

390 **Figure 3. Out-of-hospital cardiac arrest in a patient with no obstructive coronary artery**
391 **disease.**

392 Out-of-hospital cardiac arrest occurring in a 41-year-old male with biopsy-proven acute
393 myocarditis. Coronary angiography showing normal right (A) and left (B) coronary artery. Cardiac

394 magnetic resonance showing myocardial edema (two chambers, long axis view; T2-weighted
395 sequences) (C) and transmural late gadolinium enhancement (two chambers, long axis view; T1-
396 weighted inversion recovery post-contrast sequences) (D) affecting the mid-apical inferior left
397 ventricular wall.

398

399 **Figure 4. Out-of-hospital cardiac arrest in a patient with no obstructive coronary artery**
400 **disease.**

401 Out-of-hospital cardiac arrest occurring in a 29-year-old female with arrhythmic mitral valve
402 prolapse. Coronary angiography showing normal right (A) and left (B) coronary artery. Cardiac
403 magnetic resonance showing thickening and prolapse of both mitral valve leaflets (C,D), no
404 myocardial edema (three chambers, long axis view; T2-weighted sequences) (C) and evidence of
405 mid-myocardial late gadolinium enhancement (three chambers, long axis view; T1-weighted
406 inversion recovery post-contrast sequences) (D) affecting the basal infero-lateral left ventricular
407 wall behind the prolapsing posterior mitral valve leaflet.

408

409 **Figure 5. Out-of-hospital cardiac arrest in a patient with no obstructive coronary artery**
410 **disease.**

411 Out-of-hospital cardiac arrest occurring in a 36-year-old male with an isolated non-ischemic left
412 ventricular scar. Coronary angiography showing normal right (A) and left (B) coronary artery.
413 Cardiac magnetic resonance showing no myocardial edema (four chambers, long axis view; T2-
414 weighted sequences) (C) and the presence of subepicardial late gadolinium enhancement (four
415 chambers, long axis view; T1-weighted inversion recovery post-contrast sequences) (D) affecting
416 almost the entire left ventricular lateral wall.
