42 **Importance**

43 Cyanobacteria are amongst the few prokaryotes that evolved multicellularity. The early
44 emergence of multicellularity in Cyanobacteria (2.5 billion years ago) entails that some
45 unicellular cyanobacteria reverted from multicellular ancestors. We tested this evolutionary
46 hypothesis by studying the unicellular strain *Gloeocapsopsis* sp. UTEXB3054, using flow
47 cytometry, genomics and cell-to-cell communication experiments. We demonstrated the
48 existence of a well-defined patterned organization of cells in clusters during growth, which
49 might change triggered by environmental stimuli. Moreover, we found genomic signatures
50 of multicellularity in *Gloeocapsopsis* genome, giving new insights into the evolutionary
51 history of a Cyanobacterial lineage that has thrived in extreme environments since the early
52 Earth. The potential benefits in terms of resource acquisition and ecological relevance of
53 this transient behavior are discussed.

55 **Introduction**

56 Cyanobacteria have fundamentally transformed the geochemistry and biodiversity
57 on the Earth's surface. They are thought to be responsible for the rise of atmospheric
58 oxygen levels during the Great Oxidation Event around 2.4-3.2 billion years ago, enabling
59 the evolution of more complex forms of life (1, 2). Cyanobacteria have colonized most
60 terrestrial environments, thriving even in extreme environment conditions such as high UV
61 light radiation and extreme desiccation (3, 4), representing one of the most morphologically
62 diverse prokaryotic phyla. Traditionally Cyanobacteria have been classified in five different
63 morphological sections: unicellular (section I); unicellular organized in packet-like
64 structures (section II); basic filamentous forms and undifferentiated cells (section III);
65 multicellular and differentiated (section IV); and multicellular and differentiated with the
66 ability to branch in multiple dimensions (section V) (5). Moreover, among cyanobacterial
67 differentiated cells we might find hormogonia (motile cells), akinetes (a kind of spore) and
68 heterocysts (metabolically specialized cells with the ability to fix inorganic nitrogen) (6–8).

69 Cyanobacteria represent one of the few prokaryotic phyla in which multicellularity
70 evolved. Trait evolution analyses have shown that the earliest lineages of Cyanobacteria
71 were unicellular and the emergence of filamentous multicellular representatives occurred
72 very early in the evolution of Cyanobacteria (2, 9–13). Among other characters, such
73 transition required the emergence of a coordinated assembly of cells, cell-to-cell adhesion
74 and intercellular communication leading to a coordinated activity (2, 14–17). In particular,
75 filament formation in Cyanobacteria has been proposed to be the result of gain-of-function
76 mutations (18, 19), and several genes have been reported to be essential for it. For example,

77 the *fraC-fraD-fraE* operon and *sepJ* (also known as *fraG*) encode for membrane proteins
78 that are needed to produce cell-to-cell joining structures (nanopores) (20, 21) and filament
79 integrity in multicellular heterocyst-forming cyanobacteria (21–29). In the Nostocales, SepJ
80 has three well defined domains: an N-terminal coiled-coil domain, a central linker and a C-
81 terminal permease domain(19, 21); this protein is located at cell poles and it is required for
82 *Anabaena* sp. PCC7120 to form and place nanopores or septal junctions (20, 26), with
83 multimeric SepJ structures at the intercellular septa interacting with peptidoglycan (30, 31).
84 Previous studies have shown molecular exchange between the cytoplasm of cells of
85 filamentous cyanobacteria by using fluorescent tracers, especially calcein (25).
86 Furthermore, calcein-FRAP experiments comparing wild type with *sepJ* null mutants and
87 overexpressors revealed the role of SepJ in mediating intercellular molecular diffusion in
88 *Anabaena* sp. PCC7120 (19, 20, 25).

89 Other important genes in filament formation such as the cell wall amidases *amiC1*
90 and *amiC2* genes are located in tandem in *Nostoc punctiforme* genome and together have
91 also been associated to multicellular phenotypes (32, 33). The protein AmiC1 is required
92 for the correct localization of SepJ at the septum (32), and together they play important role
93 in the placement of nanopores and septal junctions (26) allowing intercellular
94 communication and heterocyst development (32, 33). AmiC2, localized within septa (34)
95 seems to be essential for multicellular development and the filament elongation in
96 *N.punctiforme*, since its knock-out mutant did not grow as a normal filamentous organism
97 but forms clusters of cells that are resistant to disintegration (35). Moreover, a common
98 minimal set of 10 genes has been proposed to be related with filament formation and/or
99 function in Cyanobacteria, including *CyDiv*, *hetR*, *patU3* and *hetZ* (18, 36).

100 Evolutionary studies have suggested that certain reversions from multi-to-
101 unicellularity occurred within the cyanobacterial phylum (10, 12, 37). One of these cases is
102 represented by the *Gloeocapsa*-like clade, comprised by cyanobacteria that have been
103 traditionally classified in the section II (unicellular cyanobacteria with packet-like
104 phenotypes). The shared ancestry with the filamentous Nostocales clade have suggested
105 that their origin was the result of the loss of some multicellular features(10, 12, 37, 38).

106 The evolutionary history of *Gloeocapsa*-like cyanobacteria suggests that
107 multicellular phenotypes (e.g., tetrads) commonly observed in unicellular cyanobacteria

108 from section II (39–41) do not represent random aggregated cells within an extracellular
109 matrix, as previously thought (42–44). Based on their evolutionary origin and morphology
110 (38), we hypothesized that *Gloeocapsa*-like cyanobacteria exhibit an intermediate
111 phenotype, with a phenotypic plasticity that allows it to behave as both multicellular
112 (adhered clusters of cells as multicellular morphotypes) and/or unicellular depending on
113 environmental conditions.

114 In this work, we studied the extremophile *Gloeocapsopsis* sp. UTEXB3054. By
115 implementing the use of flow cytometry with cell sorting and microscopy, we characterized
116 the phenotypic transitions that *Gloeocapsopsis* sp. UTEX B3054 undergoes during growth
117 in standard liquid medium as well as in modified media. We tested the phylogenomic
118 hypothesis predicting that *Gloeocapsopsis* evolved from the multicellular ancestor shared
119 with the Nostocales. We therefore looked into whether *Gloeocapsopsis* and their close
120 relatives share genes and/or genomic signatures underpinning this reversion. Our
121 comparative genomic analysis revealed that *Gloeocapsopsis* sp. UTEXB3054 retained
122 genomic features previously linked to filamentous multicellularity such as *sepJ*, *fraE*, *fraH*
123 and *CyDiv* (all2320), but lacks others such as *amiC2*. Cell-to-cell communication, hallmark
124 of heterocyst-forming cyanobacteria, was confirmed by Calcein-FRAP experiments within
125 multicellular morphotypes of *Gloeocapsopsis*. Our study provides new insights into one of
126 the few reversion events from a multicellular ancestor known to occur in nature. This event
127 gave rise to the unicellular lineage of *Gloeocapsopsis*-like cyanobacteria more than 1.6
128 billion years ago (10).

139 **Materials and Methods**

140 *Strain and culture conditions*

141 *Gloeocapsopsis* sp. UTEXB3054 was grown in 250 ml Erlenmeyer flasks
142 containing 45 ml of BG11 medium, which is widely used for the cultivation of coccoid
143 cyanobacteria (5, 45). 5 ml aliquots from stationary phase cultures were used to inoculate
144 the medium (Optical Density₇₅₀=1.0). Cultures were incubated at 28°C without agitation
145 under 10 µE of white light on a 12/12 hour light/dark cycle. Thereafter, OD was measured
146 every two days after gentle manual agitation of the cultures for homogenization. We
147 previously observed that OD₇₅₀ measurements and dry-weight are highly correlated
148 (Pearson correlation $r^2=0.99$; $P<0.0001$; not shown). OD₇₅₀ was chosen over fluorescence
149 measurements, as pigment per cell may change at the end of culture growth (increasing as
150 self-shading occurs, or sometimes declining as nutrient-limitation occurs), and precise cell
151 counts were complicated by multicellular phenotypes. For studying possible phenotypic
152 changes in cell clusters triggered by environmental stimuli, we modified the BG11 medium.
153 We used BG11 without nitrate (commonly known as BG11₀), as well as medium without
154 phosphates. The pH was always adjusted to the same as the replete BG11, and monitored
155 during growth curve. No changes in pH were observed during growth curve in these
156 modified media (data non shown). The inoculation method employed was the same
157 described above. 5 ml aliquots of stationary culture previously grown in replete medium
158 were inoculated in depleted media. The growth curves were performed using cells that have
159 been growing in reduced medium for only one cycle and without washing before
160 inoculation. The rationale behind that was to avoid any type of mechanical disturbance to
161 cell colonies due to washing the culture and to allow the culture undergo growth as it
162 responded to a chemical change in the medium. Growth experiments were performed in 3-4
163 replicates. For transmission electron microscopy (TEM) and Periodic acid-Schiff staining
164 (PAS)/ Optical microscopy, samples were processed as previously described (46).

165 *Flow cytometry and cell sorting*

166 Samples of *Gloeocapsopsis* sp. UTEXB3054 were analyzed and sorted with an
167 inFluxTM cell sorter (Cytopeia, currently manufactured by BD, Franklin Lakes, NJ, USA).
168 The samples were processed without fixation (see above) immediately after harvesting and

OD measurements. Light scatter and fluorescence were induced with 488-nm and 640-nm excitation lasers (Coherent Inc., Santa Clara, CA, USA). Scatter and fluorescence signals (580-30 nm, phycobiliproteins; 692-40 nm, chlorophyll) were detected with photomultipliers (Hamamatsu Photonics K.K.) and the current pulses were processed with logarithmic amplifiers. Digitized values of pulse heights were recorded with SortwareTM software (BD, Santa Cruz, CA, USA). The instrument was aligned and calibrated with 2 µm YG beads (Polysciences, USA) and 3 µm UltraRainbow fluorescent beads (Spherotech Inc. Libertyville, IL, USA). Alignment was considered satisfactory if the CV of bead singlets was less than 2.5%. The cytometer settings were adjusted to position the peak beads scatter and fluorescence at approximately 90% of the full scale (allowing all cyanobacteria in the cultures to be on-scale). Samples were analyzed, and cells were sorted with a 70 µm ceramic tip at a sample pressure of 1-2 psi above the sheath pressure (15 psi). Cells were run at a rate of 2000 cells/s. Fluorescence and scatter profiles were obtained by running samples for 2 minutes. For sorting the instrument was loaded with a sterile sheath fluid of 3% NaCl, that was sterilized by filtration through a 0.2 µm filter. A Sterivex filter mounted in the sheath line of the system served as a second filtration stage. Sorting of selected scatter and fluorescence regions was performed using 1-drop purity mode. Flow cytometry profiles were analyzed using FlowJo Software.

Comparative Genomic Analyses

A genomic screening was conducted in order to identify multicellular related genes in unicellular and multicellular cyanobacterial genomes. Amino acid sequences from proteins functionally characterized in *Anabaena* sp. PCC7120 were downloaded from the IMG/JGI database and used for tBLASTn (47) comparison searches (thresholds used: e-value $<10^{-25}$ and bit score >100) in other cyanobacterial genomes downloaded from same database. Code accession of cyanobacterial genomes and amino acid sequences are found in Supplementary Information Table S1.

Phylogenetic Analyses

All sequence data were obtained from GenBank (www.ncbi.nlm.nih.gov). A total of 350 cyanobacterial genomes were screened (Table S2) using *Anabaena*'s SepJ sequence as query. Gene sequences were aligned using MAFFT v7.123b (48). To investigate the

199 evolution of SepJ, we performed phylogenetic analyses based on the C-terminal permease
200 domain, conserved among homologue sequences found (this section includes the last 339
201 aa from the protein alignment found in Fig. S1). Bayesian analyses were implemented to
202 determine the phylogenetic relationships of SepJ under the CAT-GTR+G model in
203 Phylobayes MPI 1.7a (49). Convergence of Bayesian analyses was tested using the
204 software Tracecomp (in Phylobayes). In order to know position of the root in the tree,
205 different rooting options were evaluated by implementing different methodologies: (1)
206 outgroup rooting (50, 51), (2) midpoint rooting (52), and (3) Bayesian molecular clock
207 rooting (53). We used *Pseudanabaena* SepJ for outgroup rooting. The midpoint rooting
208 was estimated in R (54), and the root that minimizes the variance of root-to-tip distances
209 was estimated in TempEst v1.5.1 (55).

210 *Calcein loading*

211 Calcein is a hydrophilic molecule of 623 Da, which can be loaded into
212 cyanobacterial cells as the cell-permeant acetoxymethyl ester derivative (25). Esterase
213 activity in the cytoplasm releases a fluorescent product that is trapped in the cytoplasm
214 because it is too hydrophilic to diffuse across lipid bilayers. Intercellular exchange of
215 calcein has been monitored by confocal fluorescence recovery after photobleaching (FRAP)
216 experiments in which fluorescence is bleached in one cell (e.g. of a filament). Subsequent
217 imaging can reveal re-equilibration of fluorescent calcein between cells due to simple
218 diffusion through septal junctions: protein channels which link the cytoplasm of adjacent
219 cells in the filament (25, 56, 57). In this study, calcein was loaded into the cytoplasm of
220 *Gloeocapsopsis* cells using a protocol adapted from Mullineaux et al., 2008 (25). The
221 acetoxymethyl ester derivative of calcein (Calcein AM; Thermo Fisher Scientific) was
222 dissolved in dimethylsulfoxide to a concentration of 1mg/ml. 0.5 ml of cell culture was
223 harvested by gentle centrifugation, washed twice in fresh BG11 medium, resuspended in
224 0.5 ml fresh medium and mixed with 10 µl calcein AM solution. The cells were then
225 incubated in the dark at 28 °C for 90 min before harvesting and washing 3 times in fresh
226 BG11 medium. Small drops of cell suspension were spotted onto BG11 agar plates and
227 incubated until all the free liquid was evaporated or adsorbed. Blocks of agar with the cells
228 on the surface were cut from the plate, placed on a cover-slip and mounted in the well of a

229 custom-built sample holder.

230 *Confocal microscopy and Fluorescence Recovery After Photobleaching*

231 Cells were imaged with a Leica TCS SP5 laser scanning confocal microscope with
232 63X oil-immersion objective lens (numerical aperture 1.4). The confocal pinhole was set to
233 give a resolution in the z-direction of approximately 8 μm . Excitation was with the 488 nm
234 line of an argon laser. Monochromators were set to image calcein fluorescence at 503-515
235 nm and chlorophyll fluorescence at 670-720 nm. Bleaching was accomplished by a single
236 scan over a box of 3.8 x 3.8 μm overlapping with one cell in the field of view.

237

238 **Results**

239 *Morphology and ultrastructure of Gloeocapsopsis*

240 In nature and also when growing in liquid medium, *Gloeocapsopsis* sp. UTEX
241 B3054 appears both as single cells and forming cellular packets or clusters containing
242 between 2 and 4 cells, or even more cells (Fig. 1). Ultrastructural observations showed that
243 the EPS is concentrically organized around cells in an onion-like configuration throughout
244 the growth of *Gloeocapsopsis* sp. UTEX B3054. Clustered cells tend to be attached by
245 sugar-rich extracellular matrix (Fig. 1A) that shows blue autofluorescence (Fig. 1B),
246 forming the archetypal tetrads and packet-like clusters with multiple cells observed in
247 nature (Figs. 1C, 1E, 1F) (hereafter termed colonies and/or multicellular phenotypes). Each
248 cell is delimited by the cell wall structure typical of cyanobacteria, which is comprised by
249 the cytoplasmic membrane (CM), a peptidoglycan layer (Pg) and the outer membrane (OM)
250 (Fig. 1D). The periplasmic space between the peptidoglycan and the outer membrane was
251 not continuous among cells. Cell division occurs through equal binary fission within the
252 EPS (Fig. 1E).

253 *Changes of cellular morphotypes during growth*

254 Based on the autofluorescence of *Gloeocapsopsis* phenotypes (determined by light
255 harvesting pigments such as chlorophyll, phycocyanin and phycoerythrin) and light
256 scattering signatures of cells, flow cytometry coupled to particle sorting allowed us to
257 distinguish between single cells of *Gloeocapsopsis* sp. UTEXB3054 and its several
258 (multi)cellular phenotypes. Three main phenotypic groups of *Gloeocapsopsis* were defined
259 for further analysis: (a) single cells, (b) groups of intermediate colonies (primarily

phenotypes comprising between 2 and 4 cells) and (c) colonies with more than 4 cells (multiple or multicellular clusters) (Fig. S2). Noteworthy, single cell phenotypes (cells with the lowest light scatter signals) included two different groups of cells in terms of red (692-40 nm) and orange (580-30 nm) fluorescence when excited with blue light (488 nm) (Fig. S3). Analysis of both single cell phenotypes using the violet laser (405 nm) indicated that some of them lacked blue autofluorescence, whereas all the other *Gloeocapsopsis*'s phenotypes presented blue autofluorescence (data non shown).

The culture exhibited a consistent pattern of changes in intercellular organization during growth under replete conditions, with the highest levels of phenotypic heterogeneity occurring under active growth phase (Figs. 2 and 3). At this stage, red-fluorescent single cells significantly increased up to 20% of the total phenotypes, tending to disappear when entering into stationary phase (Table S3). Once in active growth, cellular phenotypes with intermediate light scattering properties split into two main subgroups with different light scattering properties, turning back into the distribution observed in lag-phase and early growth once in stationary phase (Fig. 3). Finally, the presence of multicellular phenotypes significantly increased under active growth (Fig. 2 and Table S3), turning back to original values once in stationary phase (Fig. 2 and Table S3).

The morphotypes exhibited by *Gloeocapsopsis* sp. UTEX B3054 changed when the chemical composition of the medium was modified (Fig. 2; dashed lines). In contrast to what was observed under replete growth, light scattering signatures of phosphate-deprived cultures were more homogeneous during the active phase of growth (Fig. 2C-D). The intermediate colonies were more prevalent in phosphate-deprived medium in comparison to standard medium, while the presence of multicellular colonies was significantly lower (Tables S3 and S4). Moreover, the orange-fluorescent single cell phenotype almost disappeared during active and stationary growth under phosphate-limited conditions (Tables S3 and S4). The intrinsic ability of *Gloeocapsopsis* to organize in different multicellular morphotypes was less affected under nitrate-deprivation (BG11₀ medium) (Tables S3 and S4). However, in BG11₀ medium there was a significant decrease in the proportion of intermediate colonies during active growth, while there was an increase in the proportion of red-fluorescent single cells during both active growth and stationary phase. The differences observed in terms of the ability to form different phenotypes under

291 different growth media were not reflected in biomass change measured by light
292 transmittance correlated to differences in biomass increase of the cultures (data non
293 shown).

294 *Comparative genomic analyses for key genes associated with multicellularity.*

295 The organized phenotypic transitions observed during *Gloeocapsopsis* growth and
296 its ability to modify the patterned growth under different chemical settings in media lead us
297 to predict that *Gloeocapsopsis* and its close relatives likely retained some multicellular
298 features which might be found in their genomes.

299 Based on genes functionally associated with multicellular abilities in Cyanobacteria,
300 we performed a genomic survey in cyanobacterial genomes. Homologues of all
301 multicellular related genes (18) were found in Nostocales genomes but were absent in
302 model unicellular cyanobacteria such as *Prochlorococcus* and *Synechococcus* (Table 1).
303 Noteworthy, Chroococceae cyanobacteria encode for some of them, including homologous
304 genes of *fraE* and *fraH* (Table 1). For instance, homologous genes of the well-described
305 *Anabaena*'s *fra*-operon were conserved in all the Nostocales cyanobacteria, although only
306 some isolated homologous genes were present in Chroococceae genomes, which lack of
307 *fraC* and *fraD*. The cell wall amidase genes *amiC1* and *amiC2* occurring in tandem were
308 found to be exclusive of Nostocales cyanobacteria (Fig. 4). In contrast to Nostocales, we
309 found that Chroococceae cyanobacteria only possess *amiC1*, lacking the adjacent gene
310 copy of the multicellular-related amidase gene (*amiC2*). However, *amiC1* in
311 Chroococceae occurred in a conserved genomic context to the Nostocales *amiC1* and
312 *amiC2*, being upstream and same orientation as a glutamate racemase (COG0796),
313 transnonapredyl diphosphate synthase (COG0142) and a transglutaminase-like putative
314 cysteine protease (COG1305) (Fig. 4).

315 *Phylogeny of SepJ*

316 A blast search using the functionally described SepJ aminoacid sequence of *Anabaena* sp.
317 PCC7120 showed that 179 of the 350 cyanobacterial genomes screened encode an
318 homologue sequence of SepJ. Strictly unicellular cyanobacteria like *Synechococcus* and
319 *Prochlorococcus* lack SepJ-like sequences. All Chroococceae cyanobacteria encode for
320 a partial or shorter homologue to *Anabaena*'s SepJ: a Drug/Metabolite Exporter (DME)-
321 family permease, with high levels of amino acid identity (34% of sequence identity and

53% of positive substitutions), lacking both the N-terminal domain with the predicted coiled-coil domain (CC) and the internal linker region (L) characteristics of the *Anabaena*'s SepJ (Table S5 and Figure S1). Bayesian phylogenetic analysis of SepJ and DME-family permease homologues found in 179 cyanobacterial genomes show that they are sister clades (Fig. 5). Within the DME-family permease clade there are some well-defined groups including Nostocales, and some cyanobacteria traditionally classified as unicellular (e.g. *Gloeocapsopsis*, *Chroococcidiopsis*). Within the SepJ clade, we found SepJ-like proteins comprised by two or three domains (CC+P; CC+L+P). The SepJ topology is consistent with previously published genome phylogenies (10) (Fig. 5; see also Fig. S4 to statistical support and posterior probabilities). Possible topology rooting options explored are illustrated in an unrooted topology (Fig. S5). SepJ variants shows that the *Pseudanabaena*-like homologue to SepJ is basal, followed by a paraphyletic group containing filamentous cyanobacteria that do not undergo any cell differentiation (e.g. *Phormidium*, *Oscillatoria*, *Leptolyngbya*) and a more recently divergent group including the Nostocales SepJ. DME-family permease sequences are found in both filamentous cyanobacteria (e.g. *Nostoc* and *Leptolyngbya*, among others) and cluster-forming unicellular cyanobacteria (e.g. *Chroococcidiopsis*, *Acaryochloris*). Interestingly, 56,7% of DME-family permeases are encoded by taxa that do also encode for long SepJ variants (*Nostoc* and *Leptolyngbya*, among others) (Table S5).

Cell-to-cell communication

We tested for the possibility of intercellular communication in dyads and tetrads of *Gloeocapsopsis* by performing calcein FRAP experiments. We found that calcein could be loaded into the cytoplasm of *Gloeocapsopsis* similarly to *Anabaena*. However, in *Gloeocapsopsis* culture only a minority of cells was successfully loaded, most probably due to the thick capsule of EPS. FRAP experiments conducted by bleaching one cell in a calcein-loaded dyad or tetrad revealed slow intercellular exchange of calcein, even when cell division appeared complete as judged from bright-field and chlorophyll fluorescence images.

Representative examples of cell-to-cell communication in dyads and tetrads are shown in Fig. 6 and Fig. S6. Calcein exchange was not detected in every case, and it occurs

352 on a slow timescale of up to a few minutes, in contrast to the faster exchange described in
353 *Anabaena* (25).

354

355 Discussion

356 Our microscopical observations indicate that *Gloeocapsopsis* cells are not randomly
357 aggregated but are organized within an extracellular matrix exhibiting an onion-like
358 structure, with the outermost EPS layer surrounding all the cells. Moreover, during active
359 growth *Gloeocapsopsis* exhibit different cellular groups corresponding to phenotypic
360 transitions, including single cells, intermediate colonies and multicellular colonies with
361 more than four cells. Although neither cell-to-cell adhesions nor membrane contact
362 between cells were observed in any of the ultrathin cuts, this cyanobacterium showed an
363 intrinsic ability to form adhered clusters of cells (multicellular phenotypes) depending on
364 growth stage and/or environmental changes. When growth is limited, *Gloeocapsopsis* sp.
365 UTEX B3054 cells arrest in dyads, triads, or tetrads, while in active growth the organism
366 appears to cycle also through single-cell stages. Our results of microscopy and flow
367 cytometry support the notion that this cyanobacterium displays a facultative or transient
368 multicellularity that might be induced in response to environmental cues.

369 Recent genomic data have improved the resolution of the Cyanobacteria phylogeny
370 (10, 12, 37). Evolutionary studies suggest that some unicellular cyanobacteria evolved from
371 a multicellular ancestor, and our comparative genomic analyses unveiled several genomic
372 signatures likely involved in the loss of multicellularity leading to origin the *Gloeocapsa*-
373 like clade. Our results suggest that the organization of multicellular phenotypes observed in
374 *Gloeocapsopsis* sp. UTEX B3054 might be reflected at the genomic level. *Gloeocapsa*-like
375 cyanobacteria do not encode homologous genes of *fraC* and *fraD*, needed for the calcein
376 transfer pathway to be operative in *Anabaena* (27) by gating the septal junctions (26).
377 However, other genes associated to filament integrity in *Anabaena* such as *fraE* and *fraH*
378 (27, 58, 59) were found in the genome of *Gloeocapsopsis* and its close relatives. Two cell
379 wall amidase genes *amiC1* and *amiC2* occurring in tandem in a preserved genomic context
380 due to a gene duplication event (60) seems to be an exclusive feature of Nostocales.
381 However, while the *Gloeocapsa*-like clade lacks *amiC2*, the genomic context is highly
382 conserved. Genetic studies have shown that *amiC2* mutants in the Nostocales affect

383 processing of septal peptidoglycan (the PG is fully split between neighboring cells in cell
384 groups), leading to less invaginated murein sacculus when comparing to wild-type cells
385 (35). The overall morphology of *amiC2* mutant in the Nostocales described in Lehner et al.
386 (2011) is somewhat similar to *Gloeocapsopsis* wild type described in this work (Fig.1E). It
387 seems that this gene duplication was a key innovation associated to the emergence of
388 diazotrophic filament-forming multicellular cyanobacteria.

389 SepJ has been described as a crucial protein during the formation of the
390 multicellular septum in filamentous cyanobacteria (19–21, 25, 30, 61). Our phylogenetic
391 analyses and rooting of SepJ and DME-family permease show that these two homologues
392 likely arose by gene duplication in a common ancestor prior to the divergence of
393 *Pseudanabaena*. Within the SepJ clade, the branching of an early basal lineage of
394 *Pseudanabaena*-like SepJ is consistent with previous phylogenomic and trait evolution
395 studies showing that *Pseudoanabaena* filamentous forms evolve early on in Cyanobacteria
396 (1, 2, 10, 12, 13, 62). The topology of SepJ is consistent with previously published genome
397 phylogenies showing the Nostocales as the most recently derived group of filamentous
398 cyanobacteria (10). SepJ and DME-permease evolved near the root of Cyanobacteria. SepJ
399 variants are only found in filamentous forms, and they must be the result of a series of gain-
400 of-function mutations, by which the protein gradually acquired the coil-coiled and the
401 linker domain and therefore, new functions (19). The permease domain represents the
402 integral membrane section of the protein and has been demonstrated to be necessary for the
403 formation of the septum junctions between cells, to participate in the intercellular
404 communication, as well as to allow proper filament elongation in diazotrophic filamentous
405 cyanobacteria (19–21, 23, 25, 30, 56, 63, 64). Due to the absence of direct cell-to-cell
406 contact in *Gloeocapsopsis* as well as the lack of diazotrophic functions, we hypothesize that
407 DME-permease participate in transport processes associated to intercellular
408 communication.

409 Our calcein-FRAP results confirm that *Gloeocapsopsis* cells carry out cell-to-cell
410 communication, previously considered a hallmark of differentiated multicellular
411 cyanobacteria (57). The results are consistent with a limited cell-to-cell communication
412 activity observed within *Gloeocapsopsis* dyads and tetrads. Such limited activity could
413 allow the intercellular diffusion of metabolites and signaling molecules, as it does in

414 filamentous cyanobacteria. We further hypothesize that some of the traditionally classified
415 unicellular cyanobacteria encoding for DME-family permease might be able to carry out a
416 still unknown mechanism of cell-to-cell communication; this could be further tested with an
417 experimental approach.

418 We propose that *Gloeocapsopsis* is not a strictly unicellular cyanobacterium but a
419 facultative multicellular organism, a biological condition that might be ecologically
420 advantageous at some stages of their life cycle or under certain environmental conditions
421 such as desiccation. If cells were highly connected, the likelihood of a catastrophic drying
422 for the whole cell cluster would greatly increase. Therefore, a transient multicellularity with
423 low levels of cell-to-cell communication may be crucial providing a limited buffering of
424 water and solute concentrations among cells, which may contribute for allowing these
425 organisms to thrive in extreme conditions such as those found in the Atacama Desert.
426 Phenotypic transitions may have evolved for mitigating some stresses (i.e., nutrient or
427 water shortage). Further research using environmentally realistic changes in nutrients and
428 water availability will help to clarify this hypothesis.

429 **Acknowledgments**

430 We thank Alejandro Munizaga (UMA-BIO) for technical support with samples preparation
431 for the TEM Microscope, and Giorgio Bianchini for technical assistance with the analyses
432 of SepJ. Phylogenetic analyses were performed at the High-Performance Computer facility
433 (BlueCrystal 4) at the University of Bristol. Funding support for PS-B came from a Royal
434 Society University Research Fellowship. LS and RV were partially supported by grants
435 from FONDECYT (1110597) and the Millennium Institute for Fundamental and Applied
436 Biology (MIFAB). CU was funded by the doctoral fellowship from CONICYT and also by
437 Beca Gastos Operacionales CONICYT 21110394. Funding support for PvD came from
438 Instituto Milenio de Oceanografía. The Influx cell sorter was purchased with FONDEQUIP
439 EQM130267.

440 **Author contributions**

441 CU, PvD, RV and PS-B designed the research. CU and GvE isolated the strain by cell
442 sorting. CU and LS maintained and prepared cultures for experiments. LS performed
443 growth curves experiments. CU, PvD, GvE performed flow cytometry experiments and
444 analyses. CU performed comparative genomic analyses under the guidance of PS-B. PS-B
445 performed the phylogenomic analyses of SepJ. CM performed FRAP experiments and
446 analyses. CU, PvD, CM, RV and PS-B wrote the manuscript. All co-authors have read and
447 contributed to the final version of the manuscript.

637 **Figure Legends**

638 **Figure 1.** Morphology and general cellular features of *Gloeocapsopsis* sp. UTEX B3054.

639 (A) Periodic acid-Schiff stained cells of *Gloeocapsopsis* sp. UTEX B3054. PAS staining
640 reveals sugar presence in both the EPS and the intracellular space. Scale bar: 4.0 μ m. (B)
641 Blue autofluorescence in extracellular polymer substances of *Gloeocapsopsis* sp. UTEX
642 B3054. Scale bar: 3.5 μ m. (C) Transmission electron photomicrograph of a characteristic
643 tetrad during the exponential phase of growth. EPS envelopes surround cells and a laminar
644 sheath is clearly distinguished enclosing only two cells. The thylakoid network is localized
645 at the cytoplasmic periphery. Scale bar: 950 nm. (D) Detail of photomicrograph shown in
646 (C). The cell wall is constituted by: the cytoplasmic membrane (CM), peptidoglycan (Pg)
647 and the outer membrane (OM). Scale bar: 173 nm (E) Cell division. Cs indicates presence
648 of carboxysome. Black arrow points to the division ring. Scale bar: 600 nm. (F)
649 Transmission electron photomicrograph of a multicellular colony, whose cells are
650 maintained together by the outermost sheath. Scale bar: 1.2 μ m.

651

652 **Figure 2.** Effect of culturing media on *Gloeocapsopsis*'s phenotypes during growth.

653 Histograms of FSC (A, C, E) and red fluorescence (B, D, F) for *Gloeocapsopsis* sp. UTEX
654 B3054. Different nutritional conditions are indicated with different line types. Replete
655 BG11 (thick solid line); nitrate-deprived culture (dotted line); and phosphate-deprived
656 culture (dashed line). Note that in these and subsequent figures, a representative replica of
657 each different nutritional treatment is shown. The frequency distribution was normalized to
658 mode. Panels (A), (B) represent *Gloeocapsopsis*'s population distribution at early growth (3
659 days after inoculation; OD = 0.1); (C), (D) represent *Gloeocapsopsis*'s population
660 distribution at mid active growth phase (8 days after inoculation; OD = 0.5) and panels (E),
661 (F) represent *Gloeocapsopsis*'s population distribution at stationary growth phase (15 days
662 after inoculation).

663

664 **Figure 3.** Intermediate phenotypes change once reaching the active phase of growth.

665 *Gloeocapsopsis* sp. UTEX B3054 population experimented dynamic changes throughout
666 time. (A), (B) and (C) Early, active and stationary phase, respectively. The initial
667 intermediate phenotypic group splits into two main subgroups once in the active phase

(shown with arrows in B). Note that in these and subsequent flow cytometry figures, only a representative replica is shown. Beads are shown as reference.

Table 1. Multicellular related genes in cyanobacterial genomes

Figure 4. *Gloeocapsopsis* sp. UTEXB3054 and its relatives are naturally-occurring knock-outs of *amiC2*.

Genomic organization of *amiC1* and *amiC2* in *S. elongatus* PCC6301, *Nostoc* sp. PCC7107, *Nostoc* sp. PCC7524, *Nostoc azzollae* 0708, *Fischerella* sp. PCC 9605, *Calothrix* sp. PCC 6303, *C. thermalis* PCC7203, *Gloeocapsa* sp. PCC7428 and *Gloeocapsopsis* sp. UTEX B3054. Genes shared are shown in color. *amiC1* is conserved in all genomes, as well as a glutamate racemase upstream, and a transnonpredyl dipshosphate synthase and a transglutaminase like putative cysteine protease downstream. In Nostocales, *amiC2* was gained likely by a gene duplication of *amiC1*. *Gloeocapsa*-like cyanobacteria lack *amiC2* in this genomic vicinity, preserving a glutamate racemase and a transnonapredyl diphosphate synthase downstream.

Figure 5. Evolution of SepJ in Cyanobacteria.

The Bayesian phylogenetic tree shown was estimated based on 171 SepJ sequences. Analyses were performed under the CAT-GTR+G model in Phylobayes MPI 1.7a (49). The topology was simplified to show the main clades of both DME-family permease and long sequences of SepJ; the corresponding tree including posterior probabilities for branch support is shown in Fig. S4, and taxa names are found in Table S5.

Figure 6. FRAP image sequence for a *Gloeocapsopsis* cell dyad loaded with Calcein-AM.

Top row: Bright-field image (grey-scale), chlorophyll fluorescence image (red) and merge of bright-field and chlorophyll fluorescence with calcein fluorescence (green). Scale-bar: 5 microns. Remaining panels show calcein fluorescence before bleaching (pre-bleach), after bleaching fluorescence in the left-hand cell (post-bleach) and then the same image with brightness enhanced for ease of visualisation. Images are then shown at the subsequent times indicated. Note that calcein fluorescence slowly equilibrates between the two cells.

699 The plot shows fluorescence in the bleached cell relative to the unbleached cell, versus
700 time. The line is an exponential curve fitted to the data points. See Fig. S6 for a second
701 representative example.
