Soil

Jonathan P. Stewart, F.ASCE⁴

Introduction

Seismic earth pressures on retaining structures have traditionally been computed using three approaches: (1) limit state methods (*e.g.*, the "Mononobe-Okabe" or M-O method and its variants), (2) elastodynamic solutions, or (3) numerical simulations. The M-O method was originally formulated by Okabe (1924) and experimentally verified by Mononobe and Matsuo (1929). This method assumes that a pseudo-static seismic coefficient (k_h) acts upon an active Coulomb-type wedge in frictional soil, which in turn results in an incremental change in the lateral earth pressure coefficient, K_{AE} , over the gravitational active earth pressure coefficient, K_A . Variants on the classical approach derived by means of kinematic limit analysis considering non-planar failure surfaces (Chen, 1975; Chen and Liu, 1990), stress fields (Mylonakis et al. 2007), retained soils with cohesion and friction (NCHRP 2008; Xu et al. 2015), and accounting for the phasing of inertial demands within the retained soil due to wave propagation (Steedman and Zeng, 1990) are conceptually alike and provide similar results for the active case. The M-O approach is the standard of practice, and has been incorporated into numerous design documents (*e.g.*, NCHRP 2008; BSSC 2009).

A problem with the M-O method lies in its inability to account for the fundamental driver of seismic earth pressures, which is relative displacement between the wall and the retained soil in the free field. Nor does the method properly account for the factors that most strongly affect relative displacements, including wall flexibility, frequency content of the ground motion, and soil-structure interaction. This includes phase differences between maximum seismic earth thrusts, which develop when the wall moves toward the retained soil, and maximum displacements which developed when the wall moves away from the soil, that cannot be captured by static considerations (Kloukinas et al. 2015). Furthermore, the method fails to produce a physically meaningful solution when k_h becomes large (*e.g.*, Mylonakis et al. 2007), a condition that is critical in seismically active regions with high design ground motion intensities. Seed and Whitman (S-W) (1970) observed that for levels of k_h up to about 0.4, the M-

43 O solution could reasonably be approximated by $K_{AE} = 0.75k_h$ (a remarkable proportionality between
44 "response" and "excitation" in a purely plastic solution). Because this equation is simple and stable, it is
45 often used in lieu of the M-O method, even when $k_h > 0.4$, which lies beyond the range intended by Seed
46 and Whitman. For example, Mikola et al. (2016) suggested that the S-W approach produced reasonable
47 predictions of seismic earth pressures acting on fixed-base cantilever walls and cross-braced basement
48 walls in centrifuge tests that produced shaking amplitudes up to about 0.75 g.

49 Elastodynamic continuum solutions such as those by Wood (1973), Veletsos and Younan (1994a,
50 1994b), Younan and Veletsos (2000), and Vrettos et al. (2016) implicitly account for factors not
51 considered in the M-O method, including excitation frequency, soil stiffness, and in some cases vertical
52 soil inhomogeneity and wall flexibility. These factors all contribute to relative displacement between the
53 wall and free-field soil, and are inherently captured in elastodynamic formulations. To facilitate tractable
54 solutions to the governing equations of motion, boundary conditions typically involve a horizontal
55 retained soil layer resting on a rigid base and the input ground motion is applied at the base of the layer.
56 These solutions tend to produce large earth pressures at the resonant frequencies of the retained soil
57 because of the large soil displacements (relative to the base) that occur at those frequencies. However,
58 for many walls the retained soil rests on materials better represented by a compliant base than a rigid
59 base. As a result, the boundary conditions required to render tractable solutions do not match the
60 boundary conditions present for most walls, and as a result, the strong resonances and associated high
61 earth pressures predicted by most elastodynamic solutions are frequently unrealistic.

62 Additional limitations of existing elastodynamic continuum solutions include lack of consideration
63 for contact nonlinearity arising from gapping between the wall and soil, and only indirect accounting for
64 material nonlinearity by selection of strain-compatible modulus and damping values using an equivalent
65 linear approach. Rigorous numerical simulations have the capability to overcome these limitations.
66 Nonlinear soil and structural behavior can be incorporated using appropriate constitutive models;

contact nonlinearity at the soil-wall contact can be included using interface elements, and compliance of the soil beneath the retained soil can be modeled by extending the depth of the domain, or using pertinent wave transmitting boundaries to represent deeper soil layers (*e.g.*, Lysmer and Kuhlemeyer 1969, Bielak et al. 2003). Nonlinear dynamic numerical simulations are recommended where feasible. However, we recognize that project time/budget constraints often do not permit nonlinear numerical simulations, and special expertise is required.

This paper extends an elastodynamic Winkler solution developed by Brandenberg et al. (2015) that eliminated the rigid base assumption by using the ground motion at the surface of the retained soil as an input rather than the motion at the base of the soil layer. The solution modeled the retaining wall as rigid and massless, and the soil as a uniform elastic continuum. Despite these limiting assumptions, it predicted seismic earth pressure resultants that agreed reasonably well with experimental data and numerical simulations. However, the distribution of seismic earth pressures did not agree well with the experimental data. This paper eliminates the assumption that the wall is rigid and massless, and models the soil as having a vertically inhomogeneous shear wave velocity. The modeling equations are formulated, the model is verified with a number of available closed-form solutions, and the model is compared with a suite of experimental data presented by Hushmand et al. (2016).

Problem Statement

The problem considered here consists of flexible wall(s) of height H retaining a soil deposit being excited by vertically propagating shear waves with surface displacement amplitude u_{g0} , as illustrated in Fig. 1. The soil is an elastic continuum with a vertically inhomogeneous shear wave velocity profile $V_s(z)$. Soil-structure interaction is represented by depth-dependent Winkler stiffness intensity $k_y^i(z)$ along the vertical walls, and the walls are constrained by rotational and translational impedance constants at the top and bottom of the wall to represent soil-structure interaction effects above and below the wall,

as well as structural components attached to the top and base of the wall that are not explicitly modeled. The walls have constant mass density, ρ_w , Poisson ratio, ν_w , thickness, t_w , Young's modulus, E_w , and plane-strain flexural stiffness, $EI = E_w t_w^3 / [12(1 - \nu_w^2)]$. Discrete masses m_t and m_b are lumped at the top and bottom of the wall, respectively, to simulate the inertia of slabs and other elements that are not modeled explicitly. Two configurations are considered: (i) an infinite length soil deposit for which the free-field displacement profile is utilized as an input, and (ii) a soil deposit of finite length L for which the displacement profile at a distance y_{ref} from the wall is employed as an input. Note that the displacement profile for configuration (ii) is influenced by the presence of the walls, and is therefore not "free-field" (unless the walls are very far apart). This condition is utilized to validate the method using experimental data. The symbol u_{go} is used to denote the ground surface motion regardless of whether it is a free-field motion, or the reference displacement at a location y_{ref} from the wall.

Input Parameters

Shear wave velocity profile

The shear wave velocity profile varies continuously with depth, z , following the form by Rovithis et al. (2011) as defined by Eq. 1,

$$V_s(z) = V_H \left[b + (1-b) \frac{z}{H} \right]^n \quad (1)$$

where V_H is the shear wave velocity at the base of the wall, n is a constant that controls the shape of the V_s profile, and b is a constant that controls the ratio of shear wave velocity at the surface, V_o , to that at the base of the wall, $b = (V_o/V_H)^{1/n}$. The shear wave velocity below depth H is not an explicit input parameter to the proposed solution, though it does influence the surface motion due to site response, and also affects the translational and rotational impedance terms at the base of the wall.

Ground motion

The ground surface motion is utilized as an input parameter, which is a departure from many elastodynamic solutions that utilize the ground motion at the base of the deposit, where a rigid boundary is assumed to exist (*e.g.*, Wood 1973, Veletsos and Younan 1994, Kloukinas et al 2012, Vrettos et al. 2016). These solutions predict large earth pressures near the natural frequencies of the soil layer resting on the rigid base (*e.g.*, Brandenburg et al. 2015). However, retained soils generally rest on materials more appropriately represented with a compliant base than a rigid one. As a result, solutions derived using a rigid base assumption will produce site responses at resonant frequencies, and associated large earth pressures, that are typically unrealistic. The proposed solution overcomes this limitation by utilizing the surface motion as an input parameter rather than the base motion. The surface motion must be selected to be consistent with the site conditions for the problem at hand, which will generally involve analysis of a soil profile that is much deeper than the retained soil. The free-field motion can be obtained from a ground response analysis using a program such as DEEPSOIL (Hashash et al. 2016), or by selecting measured ground motions consistent with seismic hazard for a particular site based on an ergodic site amplification function (*e.g.*, Seyhan and Stewart 2014).

For a given u_{g0} and angular frequency, ω , the depth-dependent displacement profile $u_g(z)$ is solved using the solution developed by Rovithis et al. (2011) as given in Eq. 2,

$$\frac{u_g(z)}{u_{g0}} = \frac{\pi}{2} \sqrt{b} s p^{\frac{1-2n}{2}} \left[J_{\alpha+1}(b^{1-n}s) N_{\alpha}(sp^{1-n}) - J_{\alpha}(sp^{1-n}) N_{\alpha+1}(b^{1-n}s) \right] \quad (2)$$

where $s = a_o / \left[(1-b)(1-n) \right]$, $p = b + (1-b) \frac{z}{H}$, $a_o = \omega H / V_H$ is a dimensionless frequency, and J_{α} and N_{α} are Bessel functions of the first and second kind, respectively, of order $\alpha = (2n-1)/(2-2n)$ (Abramowitz and Stegun, 1965).

130 Winkler stiffness intensity

131 The Winkler stiffness intensity, $k_y^i(z)$, is a function of depth, as defined by Eq. 3, where k_{yH}^i is the
 132 Winkler stiffness intensity at the base of the wall assumed rigid, and $f(z)$ is a function that defines the
 133 variation with depth. The function $f(z)$ is also used for the depth variation of shear wave velocity, except
 134 that the exponent $2n$ is introduced to account for the fact that shear modulus is proportional to V_s^2 . The
 135 value of k_{yH}^i is computed using Eq. 4, where k_{yHo}^i is the static Winkler stiffness intensity at the base of
 136 the wall based on the solution by Brandenburg et al. (2017), as defined by Eq. 5, and ζ_{freq} , ζ_{flex} , and ζ_{length}
 137 are scalar adjustment factors to account for frequency, wall flexibility, and finite deposit length
 138 respectively.

$$k_y^i(z) = k_{yH}^i \cdot f(z) = k_{yH}^i \cdot \left[b + (1-b) \frac{z}{H} \right]^{2n} \quad (3)$$

139 where,

$$k_{yH}^i = k_{yHo}^i \cdot \zeta_{freq} \cdot \zeta_{flex} \cdot \zeta_{length} \quad (4)$$

in which,

$$k_{yHo}^i = \frac{G_H}{H} \frac{2}{\sqrt{(1-\nu)(2-\nu)}} \left[1.06 \cdot e^{-1.97(1-2n)-3.01b} + \frac{\pi}{2} \right] \quad (5)$$

140 Scaling term ζ_{freq} captures the influence of wave propagation through the retained soil on the Winkler
 141 stiffness intensity, as defined by Eq. 6 (Kloukinas et al. 2012),

$$\zeta_{freq} = \sqrt{1 - \frac{a_o^2}{\hat{a}_{oc}^2}} \quad (6)$$

142 where $\hat{a}_{oc}$ is the first-mode dimensionless natural frequency for the portion of the soil deposit above
 143 the base of the wall, which potentially may be of finite length. For the case of an infinitely long soil
 144 deposit behind the wall, $\hat{a}_{oc} = a_{oc}$, which is given by Eq. 7 (Brandenburg et al. 2017).

$$a_{oc} \approx \frac{\pi}{2} - 0.406 \cdot e^{-1.95(1-2n) - 2.11b} \quad (7)$$

145 A more general solution for retained soil layers of finite length L is given by the theoretical expression in
 146 Eq. 8 (Brandenberg et al. 2017),

$$\hat{a}_{oc}^2 \approx \frac{\frac{2}{1-\nu} \frac{a_{oc}}{b_{oc} \psi_e} \left[\sinh \left(\frac{L}{H} \frac{a_{oc} b_{oc}}{\psi_e} \right) - \frac{L}{H} \frac{a_{oc} b_{oc}}{\psi_e} \right]}{2 \frac{L}{H} - \frac{3\psi_e}{a_{oc} b_{oc}} \sinh \left(\frac{L}{H} \frac{a_{oc} b_{oc}}{\psi_e} \right) + \frac{L}{H} \cosh \left(\frac{L}{H} \frac{a_{oc} b_{oc}}{\psi_e} \right)} + a_{oc}^2 \quad (8)$$

147 where $\psi_e^2 = (2-\nu)/(1-\nu)$ is a compressibility coefficient and b_{oc} is a stiffness multiplier accounting for the
 148 heterogeneity of the soil deposit (Eq. 9). For finite-length deposits, $\hat{a}_{oc} > a_{oc}$ due to the confining
 149 effect provided by the two walls. Note that $\hat{a}_{oc} = a_{oc}$ when $L = \infty$.

$$b_{oc} \approx 1 + 1.17 \cdot e^{-2.16(1-2n) - 2.97b} \quad (9)$$

150 Scaling term ζ_{flex} is required because Winkler stiffness intensity is higher for flexible walls than for
 151 rigid walls due to mobilization of shear stresses at the soil-wall interface caused by wall rotation during
 152 flexure. Continuum finite element solutions were used to develop an approximate solution for ζ_{flex} (Eq.
 153 10) that depends on a dimensionless Winkler constant β_o given by Eq. 11 (modified from Durante et al.
 154 2018).

$$\zeta_{flex} = 1 + \exp \left[1.28 + \frac{0.95 \cdot b - 1.56 \cdot n - 4.87}{(\beta_o H)^{0.80}} \right] \quad (10)$$

$$\beta_o = \sqrt[4]{\frac{k_{yH}^i}{4EI}} \quad (11)$$

155 Scaling term ζ_{length} was derived from the solution by Brandenberg et al. (2017) for two rigid walls
 156 retaining a finite-length inhomogeneous elastic soil deposit, and is given by Eq. 12. The value of ζ_{length} is
 157 larger than unity because (i) the two walls provide a stiffening effect that increases Winkler stiffness
 158 intensity, and (ii) the displacement profile at y_{ref} is smaller than in the "free-field" due to the restraining

159 effects of the walls. For a given pressure at the soil-wall interface, the Winkler stiffness intensity must
 160 therefore be higher for a reference displacement profile at y_{ref} compared with a free-field reference
 161 displacement profile. The expression in Eq. (11) goes to unity when free-field conditions are allowed to
 162 occur in the retained soil (*i.e.*, $y_{ref} \rightarrow \infty$ and $L \rightarrow \infty$). Wall flexibility likely influences the effect of
 163 deposit length on Winkler stiffness intensity, but that effect has not yet been systematically quantified.

$$\zeta_{length} = \frac{1 - \exp\left(-\frac{b_{oc}\sqrt{\hat{a}_{oc}^2 - a_o^2} L}{\psi_e H}\right)}{1 - \exp\left(-\frac{b_{oc}\sqrt{\hat{a}_{oc}^2 - a_o^2} y_{ref}}{\psi_e H}\right) + \exp\left(-\frac{b_{oc}\sqrt{\hat{a}_{oc}^2 - a_o^2} L}{\psi_e H}\right) - \exp\left(-\frac{b_{oc}\sqrt{\hat{a}_{oc}^2 - a_o^2} L - y_{ref}}{\psi_e H}\right)} \quad (12)$$

164 Wall Boundary Conditions

165 The wall is represented as an elastic Euler-Bernoulli plate with constant flexural stiffness, EI ,
 166 constrained by horizontal and rotational springs at the top and base of the wall (Fig. 1). Stiffness
 167 constants at the top and base of the wall arise from two different contributions: (i) from the soil below
 168 the base and/or above the roof diaphragm, and (ii) from structural components connected to the roof
 169 and/or base diaphragms. The equations for the springs employ a notation in which K denotes the total
 170 stiffness, which arises from the contributions from the soil, K , and from contributions from structural
 171 components connected to the top and/or bottom of the wall, K , subscript "y" denotes horizontal
 172 translational stiffness, "xx" denotes rotational stiffness, "t" denotes the top of the wall, and "b" denotes
 173 the base of the wall.

174 In the case of rigid diaphragms, $K = K$, and existing solutions are available for quantifying the
 175 forces that arise from relative displacement between the wall and the soil. Soil displacements at the top
 176 and base of the wall are $u_g(0)$, and $u_g(H)$, respectively, while soil rotations are zero for vertically
 177 propagating shear waves. Assuming the walls are attached to a rigid diaphragm of width $2B$, and the
 178 depth from the bottom of the wall to a rigid layer is D , solutions for $K_{y,b}$ and $K_{xx,b}$ for rigid footings

179 resting on uniform elastic soil are given in Eqs. 13 and 14 (modified from Gazetas and Roesset, 1976;
180 Katsiveli 2020),

$$K_{y,b} = \frac{2.1\overline{G_b}}{2-\nu} \left[1 + 3\nu(2-\nu) \frac{B}{D} \right] \quad (13)$$

$$K_{xx,b} = \frac{\pi\overline{G_b}B^2}{2(1-\nu)} \left(1 + \frac{1}{5} \frac{B}{D} \right) \quad (14)$$

181 where $\overline{G_b}$ is taken as the average shear modulus over the depth interval from H to $\min(H+B, H+D)$, and
182 is computed from the time-averaged shear wave velocity over this depth interval. Values of $K_{y,t}$ and
183 $K_{xx,t}$ are zero for the applications presented herein because the top of the wall is flush with the ground
184 surface. However, these terms would be non-zero for structures whose top is embedded beneath the
185 ground surface, and are therefore included in the formulation so that it is extensible to more deeply
186 embedded structures. For cases with flexible diaphragms, an equivalent Winkler method is used to
187 compute the flexural stiffness terms, as presented in the Appendix.

188 Governing Differential Equation

189 The governing differential equation for the wall is given by Eq. 15, where $\frac{\partial^2 u(z)}{\partial t^2} = -\omega^2 u(z)$ for a
190 harmonic motion (harmonic variation with time is implied and not explicitly written):

$$\underbrace{EI \cdot \frac{\partial^4 u(z)}{\partial z^4}}_{\text{Change in shear force with depth}} - \underbrace{k_{yH}^i f(z) [u_g(z) - u(z)]}_{\text{Earth Pressure, } \Delta\sigma} - \underbrace{\rho_w t_w \omega^2 u(z)}_{\text{Wall Inertia}} = 0 \quad (15)$$

191 A weak form approximation is adopted here to develop an analytical solution. The u_g term is first moved
192 to the right side of the expression, and both sides are multiplied by a set of depth-dependent shape
193 functions, $\Phi(z)$, and then integrated over the wall height (Eq. 16).

$$EI \int_0^H \frac{\partial^4 u(z)}{\partial z^4} \Phi_j dz + k_{yH}^i \int_0^H f(z) u(z) \Phi_j(z) dz - \rho_w t_w \omega^2 \int_0^H u(z) \Phi_j(z) dz = k_{yH}^i \int_0^H f(z) u_g(z) \Phi_j(z) dz \quad (16)$$

194 A trial displacement, $\hat{u}$, is defined as the sum of shape functions multiplied by coefficients, c_i , that have
 195 units of length (Eq. 17).

$$\hat{u} = \sum_i c_i \Phi_i \quad (17)$$

196 The solution is exact if the shape functions match the actual displaced shape of the wall, but such shape
 197 functions generally cannot be obtained. We apply Hermite cubic polynomial shape functions (Eq. 18) to
 198 approximate the displaced shape of the wall. These functions are traditionally utilized to develop
 199 stiffness matrix solutions for a Bernoulli-Euler plate (McGuire et al. 2015), and are a reasonable
 200 approximation for beams that are stiff relative to the soil, as illustrated later.

$$\Phi_i = \begin{Bmatrix} \left(1 - \frac{z}{H}\right)^2 \left(1 + 2 \frac{z}{H}\right) \\ z \left(1 - \frac{z}{H}\right)^2 \\ \left(\frac{z}{H}\right)^2 \left(3 - 2 \frac{z}{H}\right) \\ -\frac{z}{H}^2 \left(1 - \frac{z}{H}\right) \end{Bmatrix} \quad (18)$$

201 The c_i coefficients are computed as described in the Appendix, and the coefficients are substituted
 202 into Eq. 17 to obtain an approximate displacement function. Although this function provides a
 203 reasonable approximation to the displacements and rotations (the essential boundary conditions),
 204 higher derivatives required to obtain bending moment and shear (the natural boundary conditions) and
 205 earth pressure are less accurate (*e.g.*, Scott 1981). Rather, the natural boundary conditions are obtained
 206 by multiplying displacements and rotations and the ends of the wall by the appropriate “spring”
 207 stiffness. The subgrade reaction is then computed based on relative displacement between the soil and

208 the wall using Eq. 15, and subsequently numerically integrated to obtain shear and bending moment
209 diagrams.

210 The subgrade reaction expression in Eq. 15 is divided into two components; the earth pressure
211 component is the Winkler stiffness intensity multiplied by the relative displacement, and includes earth
212 pressures arising from kinematic and inertial interaction effects. The wall inertia component captures
213 the contribution to bending moment of the distributed mass along the wall height, which acts in
214 addition to the earth pressure component. The wall inertia component can be conceptualized as the
215 equivalent pressure that would have to be applied to a massless wall to generate the bending moment
216 profile produced by the distributed inertial forces acting along the wall height. The wall inertia
217 component is therefore not an externally applied pressure acting at the soil-wall interface, but rather an
218 equivalent pressure (*i.e.*, a body force) that accounts for the influence of wall inertia on bending
219 moment.

220 **Frequency Domain Solution**

221 The modeling equations formulated herein are implemented using a frequency domain approach in
222 which the surface motion time series is decomposed into its harmonic components and each frequency
223 is analyzed separately. The steps are (see also Brandenberg et al. 2015):

224 (1) compute the Fourier transform of the surface motion, Fu_{g0} .

225 (2) for each component of Fu_{g0} compute stiffness and mass matrices and force vectors and solve for $\{c\}$

226 (note there is a separate c for each frequency component).

227 (3) for each c compute reaction forces as

$$\mathbf{F}^{\text{reac}} = [\mathbf{K}^a + \mathbf{K}^b - \mathbf{M}^a] \mathbf{c} - \mathbf{F}^a \quad (19)$$

228 where $\mathbf{F}^{\text{resac}}$ is a vector consisting of the Fourier coefficients of the shear and bending moment at the
229 top and bottom of the wall. The stiffness matrices and force vectors in Eq. (19) are derived in the
230 Appendix.

231 (4) compute the inverse Fourier transform of each component of $\mathbf{F}^{\text{resac}}$ to obtain shear and moment time
232 series at the top and bottom of the wall.

233 (5) at the time of the peak bending moment, compute the soil and wall displacement at N points evenly
234 distributed along the height of the wall using Eqs. 2 and 17, respectively ($N=10$ was used for the
235 solutions presented herein).

236 (6) compute the components of earth pressure at each of the N points along the wall using Eq. 15.

237 (7) using the known shear and bending moment at the top of the wall as boundary conditions,
238 numerically integrate the pressures from (6) to obtain values of shear and bending moment at the N
239 points along the wall.

240 To facilitate implementation of the proposed solution, a Jupyter notebook and files necessary to run
241 the notebook have been published in the DesignSafe cyberinfrastructure (Brandenberg and Durante
242 2019). Published data products include a Jupyter notebook called "FrequencyDomainExamples.ipynb", a
243 Python script called "SeismicEarthPressure.py", a ground motion file from the Pacific Earthquake
244 Engineering NGA-West2 database "RSN1077_NORTHR_STM-090.DT2" (the 090 component of the
245 displacement record from the Santa Monica City Hall during the 1994 Northridge earthquake), and an
246 image file "Schematic.png" that defines the inputs to the models. Our intention in publishing these files
247 is to make the calculations easily accessible to anyone interested in using them.

248 Verification Against Published Solutions

249 In this section we compare the proposed solution with other solutions from the literature to verify
250 its suitability to evaluate seismic earth pressures, albeit for idealized conditions. The first verification is
251 against a closed-form exact Winkler solution for uniform elastic soil and a massless wall (inspired by a
252 solution developed for piles by Anoyatis et al. 2013). The second is against an elastodynamic solution
253 presented by Younan and Veletsos (2000).

254 Closed-Form Exact Winkler Solution

255 This section compares the proposed solution with a closed-form exact Winkler solution for uniform
256 elastic soil and a massless wall. By comparing with an exact Winkler solution, we are able to assess the
257 errors introduced by the weak formulation and the use of Hermite cubic polynomial shape functions. For
258 a uniform elastic soil profile, $f(z) = 1$ and $u_g(z) = \cos(kz)$, where $k = \pi/2H$ was selected to model a
259 condition in which the free-field soil displacement is zero at the base of the wall. The uniform elastic
260 solution is given by Eq. 20 (e.g., Anoyatis et al. 2013).

$$u(z) = \chi_1 e^{\beta_o z} \cos(\beta_o z) + \chi_2 e^{\beta_o z} \sin(\beta_o z) + \chi_3 e^{-\beta_o z} \cos(\beta_o z) + \chi_4 e^{-\beta_o z} \sin(\beta_o z) + \frac{k_{yt} u_{g0} \cos(kz)}{EI \cdot k^4 + k_{yt}} \quad (20)$$

261 The beam was free against translation and rotation at the top and fixed to the soil at the base (i.e., $K_{yb} =$
262 $K_{xkb} = \infty$, $K_{yt} = K_{xxt} = 0$), and the χ factors were solved to enforce these boundary conditions.

263 Figure 2 shows distributions of wall and soil displacement, seismic pressure increment, shear force,
264 and bending moment, where all quantities have been presented in dimensionless form. The solutions
265 are presented for values of $\beta_o H = 0.5, 1.0, 1.5$, and 2.0 , where the smaller values correspond to a stiffer
266 wall relative to the soil. The errors in the solution are negligible for $\beta_o H = 0.5$ and 1.0 for all of the
267 plotted data quantities, and very small for $\beta_o H = 1.5$ and 2.0 . Most reinforced concrete cantilever
268 retaining walls must be stiff enough to limit static deformations to reasonable amounts, and generally

269 have $\beta_0 H < 2$. Furthermore, the errors are most visible in the plots of displacement and seismic pressure
 270 increment, and less significant for shear and bending moment. Bending moment is considered the most
 271 important response metric for design purposes. In general, the proposed approximate solution produces
 272 excellent agreement with the closed-form solution.

273 Comparison to Elastodynamic Solution

274 Younan and Veletsos (2000) developed solutions for the dynamic response of flexible retaining walls
 275 supporting an infinitely long deposit of uniform elastic soil. We compare predictions of the model
 276 proposed herein with their solutions for flexible walls. Seismic demands are applied in the form of a
 277 horizontal static body force (corresponding to $\omega = 0$) imposed on the soil deposit. A few definitions are
 278 required to relate their results to those formulated here. First, their solutions are formulated in terms of
 279 a dimensionless stiffness parameter, d_w , that is related to $\beta_0 H$ as indicated in Eq. 21,

$$d_w = (\beta_0 H)^4 \frac{8(1-\nu_w^2)}{\pi \cdot \psi_\sigma} \quad (21)$$

280 where $\psi_\sigma = 2/\sqrt{(1-\nu)(2-\nu)}$ and ν_w is the Poisson ratio for the wall material. Younan and Veletsos
 281 (2000) utilized $\nu = 1/3$ and $\nu_w = 0.17$ in their solutions, and the same parameters are adopted here.

282 Second, their solutions utilize the horizontal acceleration at the bottom of the retained soil, $\ddot{u}_{gH}$, as
 283 a normalizing factor, whereas we utilize the free-field displacement at the ground surface. Furthermore,
 284 our solution requires an input frequency larger than 0, and therefore does not strictly apply to problems
 285 with uniform horizontal acceleration. To overcome these issues, we utilize a long wavelength in our
 286 solution, $\lambda/H = 200$, corresponding to $kH = \pi/100$. The relationship between acceleration and surface
 287 displacement is given by Eq. 22.

$$u_{g0} = \frac{\rho H^2 \ddot{u}_{gH}}{2G[1 - \cos(kH)]} \quad (22)$$

288 A comparison of the solutions is provided in Fig. 3. The pressure distributions in Fig. 3a exhibit the
 289 same general trends in which wall flexibility reduces earth pressures overall. However, the distributions
 290 for the proposed solution tend to have a smaller resultant force, P_E , with a higher line of action, h/H ,
 291 where h is the distance to the resultant from the base of the wall. This trend is consistent with the
 292 finding of Veletsos and Younan (1994) that analyses involving only the fundamental mode of soil and
 293 wall deformation predict a higher h/H than analyses involving all modes. The solution for k'_{yH} in Eq. (3)
 294 utilizes shape functions for the soil deformation profile that correspond to the first mode. Although the
 295 proposed solution over-predicts h/H and under-predicts P_E , the combined effect provides bending
 296 moment values that agree well with the solution by Younan and Veletsos (2000). The reasonable
 297 agreement is encouraging because the proposed solution is significantly simpler to implement than the
 298 series solution by Younan and Veletsos (2000), and is easily extensible to vertically inhomogeneous soil.
 299 Furthermore, continuum elastic solutions, such as those implemented by Younan and Veletsos (2000),
 300 exhibit a singularity at the top of flexible walls in which the horizontal pressure asymptotically
 301 approaches $-\infty$ (e.g., Borowicka 1939). This singularity is unrealistic for real soils and does not occur in
 302 the Winkler approximation.

303 Validation Against Experimental Data

304 Model-To-Data Comparisons

305 The proposed solution is compared with measurements from an experimental program by
 306 Hushmand et al. (2016) involving steel box structures embedded in sand as illustrated in Fig. 4. Testing
 307 was performed on the 5.5 m-radius, 400g-ton geotechnical centrifuge at the University of Colorado
 308 Boulder. Comparisons are made for three tests, with model properties summarized in Table 1. For Test
 309 2, the structure was bolted to the base of the container, whereas for Tests 1, and 4, the structures were
 310 resting on sand as illustrated in Fig. 4. Test 3 is not used here because the tactile pressure sensors did

not function properly during the test. Dry Nevada sand No. 120 ($G_s = 2.65$, $e_{min} = 0.56$, $e_{max} = 0.84$, $D_{50} = 0.13\text{mm}$, $C_u = 1.67$, $\rho = 1.6\text{Mg/m}^3$) was placed at a relative density of $D_r = 60\%$. The structures were composed of steel with $\rho = 7.87\text{ Mg/m}^3$ and $E = 200\text{ GPa}$. Assuming that the shear beam container provides harmonic boundary conditions (*i.e.*, equivalent to an infinite sequence of identical models connected to each other in series from left-to-right), the centrifuge model represents a finite length deposit with the length of the retained soil deposit equal to twice the distance from the container wall to the structure wall, such that $L = 30\text{ m}$. Furthermore, the accelerometer that recorded the surface input motion was positioned at a distance from the wall of the structure of $y_{ref} = 11\text{m}$. The structural response was measured using strain gauges mounted on the structure walls, and tactile pressure sensors placed at the interface between the sand and the structure walls.

Shear wave velocity was not directly measured in the experiments, but rather inferred from ambient vibration data. Hushmand et al. (2016) reports that the natural frequency of the soil deposit was 4 Hz for Test 2. Assuming $n = 0.25$, $b = 0.01$, and $\nu = 0.3$, which are reasonable values for cohesionless sand, the dimensionless natural frequency computed using Eq. 7 is $a_{oc} = 1.42$. The value of shear wave velocity at the elevation of the base of the wall is then computed as $V_H = 186\text{ m/s}$ using Eq. 23. The sand was prepared in the same manner for all of the tests, so the same value of V_H was used for Tests 1 and 4.

$$V_H = \frac{2\pi f_o H}{a_{oc}} [b + (1-b)]^{-n} \quad (23)$$

Time-averaged values of V_s were then computed over the depth range from H to $H+D$ for Tests 1 and 4, and values of base stiffness $K_{y,b}$ and $K_{xx,b}$ were computed using Eqs. 13 and 14. These values correspond to the full width of the base slab. Two walls are attached to the base slab (one at each end), therefore by symmetry half of the base slab stiffness is assigned to each wall. The rotational stiffness at the top of the wall was computed from the flexural stiffness of the roof diaphragm, accounting for

antisymmetry, as $K_{xx,t} = 6EI / B$ and the translational stiffness at the top of the wall was $K_{y,t} = 0$ since there were no columns or interior walls connecting the roof and floor diaphragms. The mass of the roof and floor diaphragms were lumped at the top and base of the wall, as represented by the m_t and m_b terms in the Appendix.

A sequence of earthquake ground motions was imposed on the model using the servo-controlled, electro-hydraulic shake table. The motions consisted of the following scaled horizontal records: Sylmar Converter Station component NCS52 from the 1994 Northridge Earthquake, the LGPC Station component LGP000 from the 1989 Loma Prieta Earthquake, and the Istanbul Station component IST180 from the 1999 Izmit Earthquake in Turkey. Hushmand et al. (2016) adopted a naming convention in which the motions were assigned names based on the earthquake from which they were recorded (*i.e.*, Izmit, Loma Prieta, and Northridge), and this naming convention is utilized here for consistency with the source manuscript. Three intensities were used for the Northridge motion, and are denoted Northridge-L (low intensity), Northridge-M (medium intensity), and Northridge-H (high intensity). We obtained recorded motions from the surface of the model from Dashti (personal communication, 2017). We band-pass filtered the records using an acausal Butterworth filter with high-pass corner frequency and order of 0.2Hz and 2, respectively, and low-pass corner frequency and order of 6 Hz and 5, respectively. High pass filtering was required to remove low frequency noise to obtain accurate velocity and displacement time series. The motions were also low-pass filtered to remove low-amplitude and high-frequency portions of the records, which were observed to cause undesired resonances in the computed solutions for some motions.

Softening of the models due to strong shaking was observed in the form of lengthening of the fundamental period of the soil column, therefore an equivalent linear approach was implemented for the model predictions. Hushmand et al. (2016) adopted a modulus reduction relationship by Darendeli

(2001) for the sand, and the same modulus reduction curve is adopted herein. The average shear strain in the soil over the height of the wall was obtained by taking the difference in displacement at the ground surface, and the displacement computed at the base of the wall using Eq. 2. Embedded accelerometers could conceivably be used to obtain more accurate shear strain estimates, but we did not use these sensors because we wanted our predictions to be consistent with the modeling assumption in which only the surface motion, soil properties, and structural properties are known. A strain-compatible shear wave velocity, $V_{H,eq}$, was obtained by the following steps: (1) assume a value of $V_{H,eq}$, (2) compute the soil displacement time series at the elevation of the top of the wall and of the bottom of the wall (Eq 2), (3) compute a time series of average strain over the wall height as the difference in displacements divided by wall height, and find the maximum value, γ_{max} , (4) compute a representative shear strain, $\gamma_{eff} = \gamma_{max} (M_w - 1)/10$ following Idriss and Sun (1992), where M_w is the moment magnitude for the earthquake from which the ground motion record was obtained, (5) obtain a G/G_{max} value from the modulus reduction curve, and compute $V_{H,eq} = V_H (G/G_{max})^{0.5}$, and (6) repeat steps 2 through 5 until the computed value of γ_{eff} is consistent with $V_{H,eq}$.

Predicted profiles of wall displacement, seismic earth pressure component $\Delta\sigma_k$, and bending moment M are presented in Fig. 5 for Test 2 with the Northridge-L motion, and in Fig. 6 for Test 1 with the Loma Prieta motion. The measured peak horizontal pressure and bending moment profiles are also plotted. The tactile pressure sensors and strain gauges were connected to different data acquisition systems that were not synchronized. Therefore, the measured pressure data are plotted at the time that the peak pressure was measured rather than at the time the peak bending moment was measured. The tactile pressure transducers directly measure the pressure at the soil-wall interface, and are compared in Figs. 5-6 with predicted values of $\Delta\sigma$, which represents earth pressures at the soil-wall interface. The predicted interface pressures and moments are both plotted for the time of peak bending moment.

378 The bending moment data are captured quite well by the proposed solution in this case, whereas
379 the predicted soil pressures differ from the measured soil pressures. Although we show the measured
380 earth pressures for completeness, we focus our attention on bending moments for a number of reasons.
381 First, the strain gauges are considered to provide more reliable measurements than the tactile pressure
382 sensors (Dashti, personal communication 2017). Second, because of the aforementioned time difference
383 between predicted and measured soil pressures, a match would not necessarily be expected. Third,
384 bending moments are more important from a structural perspective.

385 Also plotted in Figs. 5 and 6 are solutions corresponding to the Seed and Whitman (S-W) method,
386 and in Fig. 5 for the Mononobe-Okabe (M-O) method. A friction angle of $\phi = 35^\circ$ was utilized for these
387 solutions, as assumed by Hushmand et al. (2016). The M-O method does not produce a solution for the
388 Loma Prieta motion in Test 1 because the peak surface acceleration exceeded the M-O limiting value of
389 $PGA/g \geq \tan(\phi)$, which is 0.7g (the measured PGA was 0.81g for the Loma Prieta motion in Test 1).

390 In the application of the S-W and M-O solutions, the earth pressure distribution was assumed to be
391 triangular with the resultant acting at a height $(h/H) = (1/3)$. Seed and Whitman recommended placing
392 the resultant at $(h/H) = (0.6)$, but Mononobe and Matsuo (1929) found that $(1/3H)$ is a more suitable
393 resultant height for flexible walls. This is also consistent with recent observations by Wagner and Sitar
394 (2017). Wall inertia is not included in the calculation of bending moment for the M-O and S-W solutions,
395 which we believe is the most common approach adopted when computing bending moments arising
396 from seismic earth pressures. The influence of wall inertia on these predictions is explored in the next
397 section.

398 The S-W and M-O solutions under-predict the measured bending moments in Fig. 5, and the S-W
399 solution also under-predicts bending moments in Fig. 6. It is interesting that the S-W solution produces
400 earth pressures in Fig. 6 that agree reasonably well with the measured peak pressures, but under-

401 predicts bending moment. We attribute this to the lack of wall inertia in the S-W solution, and the
402 resultant of the measured earth pressure distribution being higher than $(h/H) = (1/3)$. The proposed
403 solution predicts lower earth pressures, but higher bending moments compared with the S-W and M-O
404 solutions. This is due to inertial interaction from the distributed mass along the wall and from lumped
405 masses at the top and bottom of the wall, which are considered in the proposed solution, but not in the
406 S-W and M-O solutions, as explored in more detail in the next section.

407 For the purpose of comparing measurements and predictions for all of the ground motions imposed
408 on the model, we compute residuals defined as the natural log of the maximum measured bending
409 moment minus the natural log of the maximum bending moment predicted at the same elevation.
410 Residuals are summarized in Table 2, and plotted in Fig. 7. For the proposed solution, the mean and
411 standard deviation of the residuals are 0.11 and 0.34, respectively. For comparison, Fig. 7(b) plots
412 residuals for the Mononbe-Okabe solution and Fig. 7(c) plots residuals for the Seed and Whitman (1970)
413 solution. The mean and standard deviation for the M-O solution are computed only for the physically
414 meaningful solutions ($PGA < 0.7g$), and are 0.29 and 0.32, respectively. The mean and standard deviation
415 for the Seed and Whitman method in this case were 0.63 and 0.29, respectively. These positive mean
416 values indicate under-prediction by approximately 26% (M-O) and 47% (S-W), whereas the proposed
417 solution produces a much lower error (10%). The standard deviations of the residuals are similar for the
418 three methods.

419

Influence of Inertial Interaction

The distributed mass of the wall and lumped masses at the top and bottom of the wall were included in the predictions using the proposed solution, but not for the M-O and S-W solutions. This raises two questions: (i) what if inertia was added to the S-W and M-O solutions, and (ii) what if inertia was removed from the proposed solution? To answer the first question, bending moments for the M-O and S-W solutions were re-computed with consideration of inertial loads; the resulting residuals are plotted in Fig. 8. The acceleration was assumed to be equal to PGA when computing these forces, and half of the wall mass was lumped at the top and half at the bottom. As expected, the computed bending moments increase, which causes the residuals to decrease. The mean value of the residuals for the M-O and S-W methods now become negative, indicating over-prediction.

To investigate the significance of inertial effects in the proposed solution, bending moment profiles were re-computed with the mass terms of the wall set to zero, which corresponds to a kinematic-only solution. Residuals for the solution without mass are plotted in Fig. 9 using solid symbols, along with residuals for the solution with mass plotted using open symbols. The mean of the residuals for the solution without mass is $\mu = 0.46$, indicating that excluding mass results in an under-prediction of bending moment. The differences in residuals with inertia and without inertia are more significant for the M-O and S-W procedures (differences in mean residuals of about 0.65-0.85, Fig. 8) than for the proposed solution (difference of 0.4, Fig. 9). This occurs because the earth pressure distribution in the proposed method is an outcome of the solution rather than a prescribed boundary condition. When wall inertia is added on top of the earth pressures computed using the M-O or S-W method, the wall displaces more in response to the inertial loading, but the earth pressures remain the same.

Distributions with depth of earth pressure and bending moment are shown in Fig. 10 for Test 2 for the Northridge-L motion for cases with and without inertia. The bending moments are larger for the simulation with inertia, but the mobilized earth pressure is smaller. The reason for this behavior is that

444 inertial loading tends to displace the wall away from the free-field soil, which causes an increase in
445 bending moment and a reduction in earth pressures. This is a fundamental aspect of soil structure
446 interaction that is captured by the proposed solution, but cannot be captured by limit equilibrium
447 methods such as M-O and S-W. Similar phasing differences between kinematic and inertial demands
448 were observed by Athanasopoulos-Zekkos et al. (2013).

449 **Conclusions**

450 A Winkler solution was formulated for the response of flexible retaining walls to vertical wave
451 propagation through inhomogeneous soils. A closed-form exact solution to the governing differential
452 equation of motion does not exist, so an approximate solution was formulated using the weak form of
453 the equation obtained by a virtual work procedure. Soil-structure interaction is modeled using non-
454 uniform Winkler stiffness intensity distributed along the wall, and impedance functions at the top and
455 bottom of the wall. Mass distributed along the length of the wall and lumped at the top and bottom of
456 the wall are included in the solution. The solution is first verified using a closed-form Winkler solution
457 for homogeneous soil, then with a more robust continuum elastodynamic solution. Finally, the proposed
458 solution is validated using measurements from a recent experimental study, and shown to produce
459 more accurate predictions than the limit state procedures that are commonly utilized in practice.

460 Predictions from the proposed solution compare favorably with experimental data, but nevertheless
461 exhibited differences between predicted and measured peak bending moment values. These differences
462 arise, in part, from limitations of the proposed method, which include:

- 463 1. Soil inelasticity is modeled using the equivalent linear (EL) method, which is a common
464 assumption made in ground response and soil-structure interaction analyses. However, the EL
465 method is known to produce erroneous estimates of ground response when shaking intensity

becomes strong (e.g., Zalachoris and Rathje 2015; Kim et al. 2016). The EL method is not only used in estimating the distribution of free-field soil displacement along the height of the wall, but also in the Winkler stiffness intensity distributed along the wall height. It is unclear the extent to which this assumption introduces errors in the predictions.

2. Contact nonlinearity may arise in the formation of gaps at the soil-wall interface (which might be more important for clayey soils), but gapping is not modeled in the proposed solution.
3. The proposed solution utilizes the Winkler assumption, which is known not to faithfully model a continuum, but is useful when the Winkler stiffness intensity is carefully selected.

In addition to these limitations that may have influenced comparisons with experimental data, the proposed solution also does not consider: (i) coupling of soil and water response in saturated fill, including effects such as soil liquefaction and ground failure, pore pressures arising at the soil-wall interface, and propagation of p-waves through the fluid phase, and (ii) nonlinear material behavior in the wall's structural elements. Limitations in the proposed method can be overcome using numerical analyses specifically formulated for a particular problem.

Structural components that are not explicitly modeled in the proposed solution are represented by lumped mass and stiffness terms. This modeling approach may be inadequate for cases where a structure attached to the top of the wall(s) or base slab exhibits a dynamic response that contributes additional inertial forces to the walls. This additional inertial interaction may contribute significantly to mobilized earth pressures, and can be modeled using techniques described by NIST (2012).

We advocate that the seismic response of retaining walls should be assessed using procedures that properly account for aspects of soil-structure interaction that strongly influence response. Limit state procedures, such as the Mononobe-Okabe method and Seed and Whitman method, that have been commonly utilized for nearly the past century, are not formulated to consider relative wall-soil

displacement as a driver of seismic earth pressure. As a result, they do not account for important factors that influence relative displacements and the wall pressures they produce such as wall flexibility, soil inhomogeneity, and frequency content of the ground motion. Moreover, the M-O procedure does not provide a physically meaningful solution when the input acceleration becomes larger than a threshold value, which often occurs in high seismicity regions. The proposed solution, by contrast, considers wall flexibility, soil inhomogeneity, and ground motion frequency content, which results in more accurate predictions.

Acknowledgments

This study benefitted from access to data from the experimental program described in Hushmand et al. (2016). Partial support for the second author was provided by Caltrans under contract number 65A0413.

Appendix. Derivation of Stiffness matrix, mass matrix, and force vector expressions.

To avoid disrupting the flow of the paper, derivations of the weak form of the governing differential equation, and the resulting stiffness matrices, mass matrices, and force vectors are presented in this appendix. The weak form of the governing differential equation is obtained by twice integrating by parts the first term on the left side of Eq. 16, resulting in Eq. 24.

$$EI \frac{\partial^3 u(z)}{\partial z^3} \Phi_j(z) \Big|_0^H - EI \frac{\partial^2 u(z)}{\partial z^2} \frac{\partial \Phi_j(z)}{\partial z} \Big|_0^H + EI \int_0^H \frac{\partial^2 u(z)}{\partial z^2} \frac{\partial^2 \Phi_j(z)}{\partial z^2} dz + \dots$$

$$\dots + k_{yH}^i \int_0^H f(z) u(z) \Phi_j(z) dz - \rho_w I_w \omega^2 \int_0^H u(z) \Phi_j(z) dz = k_{yH}^i \int_0^H f(z) u_g(z) \Phi_j(z) dz \quad (24)$$

505 Substituting Eq. 17 into Eq. 24 for $u(z)$, results in Eq. 25. Various terms in Eq. 25 have been assigned as
 506 either a stiffness matrix, $\mathbf{K}$, mass matrix, $\mathbf{M}$, or force vector, $\mathbf{F}$, and the c_i coefficients have been
 507 algebraically isolated in each expression.

$$\begin{aligned}
 & \overbrace{EI \cdot \frac{\partial^3 u(z)}{\partial z^3} \Phi_j(z) \Big|_0^H - EI \cdot \frac{\partial^2 u(z)}{\partial z^2} \frac{\partial \Phi_j(z)}{\partial z} \Big|_0^H}^{\mathbf{F}^{\text{resc}}} + \overbrace{c_i \cdot EI \int_0^H \frac{\partial^2 \Phi_i(z)}{\partial z^2} \frac{\partial^2 \Phi_j(z)}{\partial z^2} dz}^{\mathbf{K}^a} + \dots \\
 & \dots + \underbrace{c_i \cdot k_{yH}^i \int_0^H f(z) \Phi_i(z) \Phi_j(z) dz}_{\mathbf{K}^b} - \underbrace{c_i \cdot \rho_w t_w \omega^2 \int_0^H \Phi_i(z) \Phi_j(z) dz}_{\mathbf{M}^a} = \underbrace{k_{yH}^i \int_0^H f(z) u_g(z) \Phi_j(z) dz}_{\mathbf{F}^a}
 \end{aligned} \tag{25}$$

508 The expression for $\mathbf{K}^a$ is provided by Eq. 26, and represents the traditional stiffness matrix for an Euler-
 509 Bernoulli flexural plate of unit width.

$$K_{ij}^a = EI \int_0^H \Phi_i(z) \Phi_j(z) dz = \frac{EI}{H^3} \begin{bmatrix} 12 & 6H & -12 & 6H \\ 6H & 4H^2 & -6H & 2H^2 \\ -12 & -6H & 12 & -6H \\ 6H & 2H^2 & -6H & 4H^2 \end{bmatrix} \tag{26}$$

510 The expression for $\mathbf{K}^b$ was obtained using integration by parts and the general Leibniz rule for
 511 differentiation of products of functions (*e.g.*, Olver 2000), and is given by Eq. 27. Although this
 512 expression is exact, its implementation may be susceptible to floating point errors. The equation was
 513 numerically integrated by the trapezoidal rule herein to avoid these errors.

$$K_{ij}^b = k_{yH}^i \int_0^H f(z) \Phi_i(z) \Phi_j(z) dz = \sum_{a=0}^6 \left\{ \sum_{k=0}^a \left[\frac{a!}{k!(a-k)!} \Phi_i^{(a-k)}(z) \cdot \Phi_j^{(k)}(z) \right] \frac{\left[b + (1-b) \frac{z}{H} \right]^{2n+a+1}}{(b-1)^{a+1} \prod_{m=1}^{a+1} (2n+m)} \right\} \Big|_{z=0}^H \tag{27}$$

514
 515 The mass matrix $\mathbf{M}^a$ is given by Eq. 28, and represents the contribution of distributed mass along the
 516 wall.

$$M_{ij}^a = \rho_w t_w \int_0^H \Phi_i(z) \Phi_j(z) dz = \frac{\rho_w t_w}{420} \begin{bmatrix} 156H & 22H^2 & 54H & -13H^2 \\ 22H^2 & 4H^3 & 13H^2 & -3H^3 \\ 54H & 13H^2 & 156H & -22H^2 \\ -13H^2 & -3H^3 & -22H^2 & 4H^3 \end{bmatrix} \quad (28)$$

517 The expression for the force vector $\mathbf{F}^a$ is given by Eq. 29. This expression is not integrable, and was
 518 solved using numerical integration by the trapezoidal rule.

$$F_j^a = k_{yH} \int_0^H f(z) u_s(z) \Phi_j(z) dz \quad (29)$$

519 Having solved for the stiffness matrices, mass matrix, and force vector terms in Eq. 26, the remaining
 520 task is to solve for the first two terms (*i.e.*, the natural boundary conditions) that arise from integration
 521 by parts. Evaluating these terms over the limits results in a vector of shear and moment reaction forces
 522 at the top and base of the wall given by $\mathbf{F}^{\text{reac}} = EI \left\{ \frac{\partial^3 u(0)}{\partial z^3} \quad \frac{\partial^2 u(0)}{\partial z^2} \quad \frac{\partial^3 u(H)}{\partial z^3} \quad \frac{\partial^2 u(H)}{\partial z^2} \right\}^T$. These reaction forces are
 523 represented as a function of the nodal displacement coefficients, c_i , by creating stiffness matrices, a
 524 mass matrix, and a force vector representing the springs and lumped masses at the top and base of the
 525 wall.

526 The expression for $\mathbf{K}^c$ represents the total stiffness imposed at the top and base of the wall, and
 527 contains contributions from the soil, $\mathbf{K}_s$, and from structural components connected to the top and
 528 base of the walls, $\tilde{\mathbf{K}}$. We acknowledge that many structural configurations may exist, but we restrict
 529 our treatment of these stiffness terms to a box structure with a roof and base diaphragm connecting
 530 two walls, as tested by Hushmand et al. (2016). In this case, the roof and floor diaphragms do not
 531 provide any translational stiffness because they are zero force members due to anti-symmetry of the
 532 seismic loading condition. Of course, the diaphragms do attract axial loads for the symmetric gravity
 533 loading condition. Therefore, $\tilde{K}_{y,t} = \tilde{K}_{y,b} = 0$, and $K_{y,t} = \hat{K}_{y,t}$ and $K_{y,b} = \hat{K}_{y,b}$. In cases where the roof
 534 diaphragm is flush with the surface, $K_{y,t} = 0$.

535 The roof and base diaphragms provide rotational stiffness at the base of the walls via moment resisting
 536 connections. When the base diaphragm is rigid (*i.e.*, $\tilde{K}_{xx,b} = \infty$), the walls are constrained only by the
 537 soil stiffness such that $K_{xx,b} = \hat{K}_{xx,b}$, and Equation 14 may be used. In the case of a flexible base
 538 diaphragm rotational resistance arises from the combined effects of the structural stiffness of the
 539 diaphragm and the soil stiffness, and additional steps are required to compute the combined stiffness
 540 provided by the soil and the structural components. The approach adopted herein is to compute a
 541 uniform Winkler stiffness intensity for springs acting on the diaphragm such that the rotational stiffness
 542 provided by the Winkler springs is $K_{xx,b}$, as shown in Eq. 30.

$$k_{z,b}^i = \frac{24K_{xx,b}}{B^3} \quad (30)$$

543 The combined rotational stiffness, $K_{xx,b}$, is then computed by imposing a unit rotation on the nodes at
 544 the ends of the base diaphragm and solving for the bending moment, which results in Eq. 31, where
 545 $\beta_b = \sqrt[4]{k_{z,b}^i / 4EI_b}$, and EI_b is the flexural stiffness of the base diaphragm.

$$K_{xx,b} = 2\beta_b EI_b \frac{1 + e^{-4\beta_b B} - 2e^{-2\beta_b B} \cos(2\beta_b B)}{1 - e^{-4\beta_b B} - 2e^{-2\beta_b B} \sin(2\beta_b B)} \quad (31)$$

546 For embedded structures, Eq. 32 may also be applied to the roof diaphragm by simply substituting the
 547 subscript 't' for 'b'. However, the roof diaphragm for cases analyzed herein were flush with the ground
 548 surface such that $K_{xx,t} = 0$. In this case rotational restraint arises only from the structural resistance
 549 provided by the roof diaphragm and $K_{xx,t} = \tilde{K}_{xx,t} = \frac{3EI_t}{B}$, which is the stiffness for an Euler-Bernoulli
 550 plate and also the limit of Eq. 31 as $\beta_b \rightarrow 0$

551 Noting that $u_3 = u_g(0)$, $\theta_3 = 0$, $u_4 = u_g(H)$, and $\theta_4 = 0$, expressions for $\mathbf{K}^c$ and $\mathbf{F}^c$ are given by Eqs. 32 and
 552 33.

$$\mathbf{K}^c = \begin{bmatrix} K_{y,d} & 0 & 0 & 0 \\ 0 & K_{xx,d} & 0 & 0 \\ 0 & 0 & K_{y,b} & 0 \\ 0 & 0 & 0 & K_{xx,b} \end{bmatrix} \quad (32)$$

$$\mathbf{F}^c = \begin{Bmatrix} \hat{K}_{y,d} \cdot u_g(0,t) \\ 0 \\ \hat{K}_{y,b} \cdot u_g(H,t) \\ 0 \end{Bmatrix} \quad (33)$$

553 The masses lumped at the top and bottom of the wall result in the mass matrix, $\mathbf{M}^b$ in Eq. 34.

$$\mathbf{M}^b = \begin{bmatrix} m_t & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & m_b & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad (34)$$

554 Values of shear and moment at the top and bottom of the wall are then computed using Eq. 35.

$$\mathbf{F}^{\text{resc}} = \mathbf{K}^c - \omega^2 \mathbf{M}^b \mathbf{c} - \mathbf{F}^c \quad (35)$$

555 Substituting Eq. 35 into 25 and collecting terms results in Eq. 36. Values of $\mathbf{c}$ are then solved by matrix
556 inversion.

$$\mathbf{c} = [\mathbf{K}^a + \mathbf{K}^b + \mathbf{K}^c - \omega^2 \mathbf{M}^a - \omega^2 \mathbf{M}^b]^{-1} \{\mathbf{F}^a + \mathbf{F}^c\} \quad (36)$$

658 **Figure 1.** Schematic showing flexible wall(s) retaining (a) an infinite-length soil deposit, and (b) a finite-
659 length soil deposit of (c) vertically inhomogeneous soil being shaken by (d) a ground motion with
660 surface amplitude u_{g0} .

661 **Figure 2.** Distributions of dimensionless quantities including (a) wall and soil displacement, (b) seismic
662 pressure increment, (c) shear force, and (d) bending moment.

663 **Figure 3.** Comparison of proposed solution with Younan and Veletsos (2000) showing (a) dimensionless
664 pressure distributions, (b) dimensionless soil thrust, (c) dimensionless line of action of resultant, and
665 (d) dimensionless overturning moment.

666 **Figure 4.** Experimental configuration scheme (modified after Hushmand et al. 2016).

667 **Figure 5.** Predicted and measured response quantities for the Northridge-L motion applied to Test 2.

668 Predictions include the method proposed in this study ("predicted"), the Mononobe-Okabe method
669 ("M-O"), and by Seed and Whitman ("S-W"). The measured values of $\Delta\sigma$ were obtained by pressure
670 cells, and values of M were evaluated from strain gauge data.

671 **Figure 6.** Predicted and measured response quantities for the Loma Prieta motion applied to Test 1.

672 Predictions include the method proposed in this study ("predicted") and by Seed and Whitman ("S-
673 W"). The Mononobe-Okabe method did not produce a solution for this motion.

674 **Figure 7.** Residuals for the proposed solution, the Mononobe-Okabe method, and the Seed and
675 Whitman method.

676 **Figure 8.** Residuals for (a) the Mononobe-Okabe method with and without wall inertia, and (b) the Seed
677 and Whitman method with and without wall inertia. Values of μ and σ are computed for the cases
678 with wall inertia.

679 **Figure 9.** Residuals for proposed solution with and without wall inertia. Values of μ and σ are computed
680 for the cases without wall inertia.

681 **Figure 10.** Distributions of soil and wall displacement, seismic earth pressure, and bending moment for
682 the Northridge-L motion for Test 2 for simulations with and without inertia loading.
