1) NO\textsubscript{2} lineshapes in solution

The lineshape of the $\nu_3$ transition is subtly different in each solvent, with regards to the central wavenumber, homogeneous linewidth, and hindering of free rotation (measured by the Q: P/R branch ratio) as presented in Figure 1.\textsuperscript{1} Analysis of the lineshapes therefore provides valuable information about the local solvent environment.

Large solute translational energy leads to homogeneous line broadening in transient spectra due to the increased frequency of perturbing interactions with the solvent cage. Furthermore small solute rotation has been shown to be relatively unhindered in perfluorocarbon (PFC) solutions, leading to the observation of significant P and R rotational band structure in the absorption spectrum. Indeed the final equilibrated lineshape of the NO\textsubscript{2} $\nu_3 = 1 \leftrightarrow 0$ transition cannot be fit with a single Voigt profile. The initial homogeneous linewidth of the NO\textsubscript{2} transitions following N\textsubscript{2}O\textsubscript{4} photolysis in perfluorohexane solution is approximately 39 cm\textsuperscript{-1}, and narrows to its final width of 15.6 ± 0.3 cm\textsuperscript{-1} after about 5 ps. This timescale is consistent with previously measured rotational / translational energy relaxation in perfluorohexane.\textsuperscript{1}

The lineshapes observed are best fit with a combination of a Lorentzian broadened gas phase simulation of the rotationally structured absorption band of the antisymmetric stretch of NO\textsubscript{2} and a single Lorentzian function at the central transition wavenumber. The gas phase simulation used rotational constants which remained unchanged under vibrational excitation (A = 8.0 cm\textsuperscript{-1}, B = 0.42 cm\textsuperscript{-1}, C = 0.42 cm\textsuperscript{-1}). The NO\textsubscript{2} $\nu_3$ central transition wavenumber is shifted from the observed gas phase value of 1617 cm\textsuperscript{-1} \textsuperscript{2} to approximately 1609 cm\textsuperscript{-1} in PFC solvents and 1603 cm\textsuperscript{-1} in chloroform. The magnitude of the observed shift in the central wavenumber is related to the solvent solute interactions. A small change in the shift in centre wavenumber is observed in PFCs, increasing from perfluorohexane to perfluoromethylcyclohexane and perfluorodecalin, in addition to an increase in the relative contribution of the central Lorentzian component for the lineshape. The ratio of the integrated area of the central Lorentzian to the gas phase simulation component can be related to the energetic barrier to rotation of NO\textsubscript{2} provided by the solvent.\textsuperscript{1}

This barrier quantifies the degree to which the solvent perturbs the rotational motion and subsequently the vibrational spectrum of NO\textsubscript{2}. The small observed solvent dependence suggests a minimal increase in van der Waals forces in PFCs consistent with the trend of increasing boiling point from perfluorohexane to perfluorodecalin. \textsuperscript{3,4}
Figure S1: Experimental lineshapes of NO$_2$ $v_3$ absorption (black circles) are fit with a combination (black line) of a single Lorentzian at the centre wavenumber (brown line) and Lorentzian broadened gas phase simulation (green line) of NO$_2$ $v_3$ absorption in (a) perfluorohexane, (b) perfluorodecalin, (c) chloroform.

The Lorentzian full width half maximum (FWHM) observed for the NO$_2$ $v_3$ absorption narrows considerably from perfluorohexane ($15.6 \pm 0.3$ cm$^{-1}$) to chloroform ($11.0 \pm 0.2$ cm$^{-1}$). All the absorptions are Lorentzian broadened demonstrating that homogeneous broadening dominates the lineshape. The FWHM of the NO$_2$ $v_3$ absorption observed in chloroform is similar to that observed in perfluorodecalin ($11.3 \pm 0.3$ cm$^{-1}$) despite a significantly larger central wavenumber.
shift and ratio of the central Lorentzian to the gas-phase like component observed in chloroform suggesting that the NO$_2$ absorption undergoes motional narrowing in chloroform. The increase in FWHM of the NO$_2$ $v_3$ absorption from perfluorodecalin (11.3 ± 0.3 cm$^{-1}$) to perfluoromethylcyclohexane (14.4 ± 0.4 cm$^{-1}$) to perfluorohexane (15.6 ± 0.3 cm$^{-1}$) is more difficult to explain given the similarity of the PFC solvents and their weak interactions with solutes.

2) Transient vibrational absorption (TVA) spectra

![Figure S2: Animation of the time-dependence of the TVA spectra of NO$_2$ in (from top) chloroform, d-chloroform, carbon tetrachloride, perfluorohexane, perfluorodecalin and perfluoromethylcyclohexane.](image)

Figure S2: Animation of the time-dependence of the TVA spectra of NO$_2$ in (from top) chloroform, d-chloroform, carbon tetrachloride, perfluorohexane, perfluorodecalin and perfluoromethylcyclohexane.
Figure S3: TVA spectra in the NO$_2$ antisymmetric stretch region following photolysis of N$_2$O$_4$ in chloroform.

Figure S4: TVA spectra following photolysis of N$_2$O$_4$ in CDCl$_3$ (top) and CHCl$_3$ (bottom) showing antisymmetric stretch absorption of highly excited NO$_2$ as early time (blue) features that evolve to higher wavenumber as the NO$_2$ cools (orange). After ~300 ps these features have shifted out of the observation window, but can be seen in Figure S2.
Figure S5: Transient spectra of the antisymmetric stretch of NO₂ produced from N₂O₄ photodissociation at 340 nm in perfluorodecalin solution. The black lines show the experimental spectra which have been fit to a Boltzmann distribution of NO₂ vibrational states shown as the red dotted lines. The total spectral feature can be fit by a single Boltzmann distribution from time delays of 150 ps the temperature of which decays exponentially with time.

3) Concentration dependence of transient data

N₂O₄ exists in the gas phase in equilibrium with NO₂. The N₂O₄ molar dissociation constant (K_c = 0.0060) shows that N₂O₄ is the dominant species in the gas phase at 298 K. The normal molarity ([c]) corresponds to 1 mol dm⁻³.

\[ N_2O_4 \rightleftharpoons 2NO_2 \]

\[ K_c = \frac{[NO_2]^2}{[N_2O_4][c]} \]

When dissolved in solution the equilibrium constant shifts significantly further in favour of N₂O₄. Values of K_c have previously been determined in chloroform (K_c = 5.3 \times 10^{-6}) and carbon tetrachloride (K_c = 5.9 \times 10^{-6}). The concentration of N₂O₄ can be determined from a given concentration of NO₂ moieties ([c_{NO₂}]) present using:

\[ \frac{[N_2O_4]}{4 \times \left( \frac{c_{NO_2}}{c_c} \right) + K_c - \sqrt{8K_c \times \left( \frac{c_{NO_2}}{c_c} \right)} + K_c^2} \]

Concentration dependent transient absorption measurements of N₂O₄ photodissociation were conducted by dilution of saturated solutions to reduce the relative concentration of NO₂ in carbon tetrachloride and perfluorohexane. The growth of the ground state absorption of the
antisymmetric stretch of NO₂ was followed after 100 ps by integrating the high wavenumber side of the $v_3 (1\rightarrow0)$ transition. The exponential time constant for the growth of the $v_3 (1\rightarrow0)$ transition was plotted against relative concentration of N₂O₄ (as determined by dilution factors). The linear decrease in time constant with N₂O₄ concentration shown in Figure S6 suggests that vibrational relaxation of NO₂ is somewhat enhanced through interaction with N₂O₄ molecules.

Figure S6. Linear fits to the change in exponential time constants for the growth of the $v_3 (1\rightarrow0)$ transition of NO₂ produced through 340 nm excitation of N₂O₄ at various relative concentration of N₂O₄ in CCl₄ (green, top panel) and perfluorohexane (red, bottom panel). Error bars are calculated as twice the standard deviation in time constants extracted from integrating the high wavenumber side of the $v_3 (1\rightarrow0)$ band of NO₂.

The extrapolated time constants at zero concentration (780 ps in CCl₄ and 167 ps in perfluorohexane) result from interaction of NO₂ with solvent molecules only. They identify a much longer relaxation time scale in carbon tetrachloride than in perfluorohexane, consistent with the analysis in the main text. The gradient of the concentration dependence is approximately seven times larger in magnitude in CCl₄ than perfluorohexane. This difference could reflect different diffusion timescales, but is better explained by an approximately 7 times higher saturation concentration of NO₂ in CCl₄.

Similar analysis of the high wavenumber side of the $v_3 (1\rightarrow0)$ transition in the transient absorption data used to determine thermal cooling time coefficients in the main paper suggests that the N₂O₄ concentrations correspond to points of the graphs in Figure S6 for N₂O₄ relative concentration of approximately 0.25 in perfluorohexane and less than 0.05 in CCl₄. This correlates
well with the expectation of approximately the same N$_2$O$_4$ concentration in both solvents given the 7-fold greater solubility in CCl$_4$. Furthermore, the deviation of the time constant for growth of the $v_3$ (1←0) transition at relative N$_2$O$_4$ concentrations of 0.25 (PFH) and 0.05 (CCl$_4$) from zero concentration (~20 ps) is relatively small compared to the vibrational time constants investigated in the main text suggesting that semi-quantitative comparison between the datasets in different solvents is reasonable.

4) IR pump – IR probe data

Transient infrared pump – infrared probe experiments were conducted on the antisymmetric stretch of solvated NO$_2$. An IR pump pulse centred at 6300 nm vibrationally excited NO$_2$ $v_3$ (1←0) which was then probed by a second equivalent IR pulse. The recovery of the ground state was fit to a bi-exponential (or a single exponential in PFCs). The recovery of ground state NO$_2$ in CHCl$_3$ was dominated by a 23 ± 2 ps (24 ± 3 ps in CDCl$_3$) time constant, recovering approximately 90 % of the population. A slower time constant on the order of 300 ps was responsible for the remainder of the population recovery. Similarly in CCl$_4$ a fast recovery (62 ± 10 ps) of 67 % of the population was followed by a recovery with a timescale on the order of a nanosecond.

Figure S7. Transient IR-pump IR-probe spectra of the antisymmetric stretch of NO$_2$ excited to $v_3 = 1$ in CCl$_4$. Spectra are plotted for time delays from 0.5 (blue) to 900 ps (yellow).

The main text explains the faster component of the relaxation of the NO$_2$ anti-symmetric stretch through anharmonic coupling to the solvent as a result of dipolar interactions. However, if the complexation energy is small, a significant fraction of the NO$_2$ molecules may not be complexed to the solvent prior to excitation and so are unable to relax their vibrational energy as efficiently, giving the slower relaxation components identified above. The slower time constants are closer to the timescales observed for the growth of the $v_3$ (1←0) transition in the UV photolysis of N$_2$O$_4$ (> 1 ns for CCl$_4$; 180 ps for CDCl$_3$; and > 1 ns for CHCl$_3$). If the faster and slower time constants for vibrational relaxation are attributed to complexed and uncomplexed NO$_2$, the relative populations would reflect the relative binding energies. Subsequently the cooling of the hot NO$_2$ produced by N$_2$O$_4$ photolysis in chlorinated solvents is better represented by the uncomplexed NO$_2$ relaxation behaviour.
Figure S8. Bleach intensities of the NO₂ antisymmetric stretch band following excitation to \( v_3 = 1 \), showing time-dependent recovery in CCl₄ (green), perfluorodecalin (black), CHCl₃ (purple) and CDCl₃ (light blue). The lines are fits to the bleach intensity data (circles) using bi-exponential functions in chlorinated solvents and a single exponential for perfluorodecalin.

In perfluorodecalin the recovery of the ground state NO₂ occurs with a single time constant of 89 ± 7 ps which is similar to the 120 ± 30 ps observed for the growth of the \( v_3 (1\leftarrow0) \) transition in the UV photolysis of N₂O₅. This outcome is consistent with an absence of dipolar interactions between NO₂ and PFCs, and hence only a weak propensity to form solute-solvent complexes.

5) Binding energy calculations

NO₂ – CHCl₃ and NO₂ – CCl₄ complex structures were computed using the Gaussian 09 program. Unrestricted DFT and MP2 methods were used to optimize geometries and calculate binding energies, with account for basis set superposition error using the counterpoise method. Table S1 shows representative values obtained at different levels of theory. The binding energies calculated varied between methods, but are typically smaller than a single quantum of NO₂ antisymmetric stretch vibrational energy, and are smaller for the NO₂ – CCl₄ interaction—consistent with the trend in complexed vs uncomplexed solute ratio implied by the bleach recovery data in section 4 (above).
