Model averaging in ecology: a review of Bayesian, information-theoretic, and tactical approaches for predictive inference

CARSTEN F. DORMANN, JUSTIN M. CALABRESE, GURUTZETA GUILLERA-ARBOITZ, ELENI MATECHOU, VOLKER BAHN, KAMIL BARTON, COLIN M. BEALE, SIMONE CIUTI, JANE ELITE, KATHARINA GERSHNER, JEROME GUELAT, PETR KEIL, JOSE J. LAHOZ-MONFORT, LAURA J. POLLOCK, BORIS SCHRODER, WILFRIED THILLER, DAVID I. WARTON, BRENDAN A. WINTLE, SIMON N. WOOD, RAFAEL O. WUEST, AND FLORIAN HARTIG

Abstract. In ecology, the true causal structure for a given problem is often not known, and several plausible models and thus model predictions exist. It has been claimed that using weighted averages of these models can reduce prediction error, as well as better reflect model selection uncertainty. These claims, however, are often demonstrated by isolated examples. Analysts must better understand under which conditions model averaging can improve predictions and their uncertainty estimates. Moreover, a large range of different model averaging methods exists, raising the question of how they differ in their behaviour and performance. Here, we review the mathematical foundations of model averaging along with the diversity of different model averaging methods exists, raising the question of how they differ in their behaviour and performance. Here, we review the mathematical foundations of model averaging along with the diversity of different model averaging methods. When averaging a set of models with many inadequate models, however, estimating model weights will typically be superior to equal weights. We also investigate the quality of the confidence intervals calculated for model-averaged predictions, showing that they differ greatly in behaviour and seldom manage to achieve nominal coverage. Our overall recommendations stress the importance of non-parametric methods such as cross-validation for a reliable uncertainty quantification of model-averaged predictions.

Key words: AIC weights; ensemble; model averaging; model combination; nominal coverage; prediction averaging; uncertainty.

Manuscript received 1 December 2016; accepted 6 February 2018. Corresponding Editor: Perry de Valpine.
Models are an integral part of ecological research, representing alternative, possibly overlapping, hypotheses (Chamberlin 1890). They are also the standard approach to making predictions about ecological systems (Mouquet et al. 2015). In many cases, it is not possible to clearly identify a single most-appropriate model. For instance, process-based models may differ in the specific ways they represent ecological mechanisms, without a clear empirical or theoretical reason to prefer one option over the other. Statistical analyses rarely offer a single solution, both because the limited amount of data allows for several plausible combinations of predictors, and because different modelling approaches are available for statistical analysis (e.g., Hastie et al. 2009, Kuhn and Johnson 2013).

Model averaging seemingly solves this dilemma. Proponents of this approach have claimed that calculating a weighted average of the predictions of all candidate models will reduce prediction error through reduced variance and bias (the latter based on arguments described in Madigan and Raftery 1994), as well as better represent uncertainty about model parametrisation and structure (Wintle et al. 2003, see also Model averaging (typically) reduces prediction errors). For some ecological examples of model averaging, see Thuiller (2004), Richards (2005), Brook and Bradshaw (2006), Dormann et al. (2008), Diniz-Filho et al. (2009), Le Lay et al. (2010), Garcia et al. (2012), Cariveau et al. (2013), Meller et al. (2014), and Lauzeral et al. (2015).

Evaluating the utility of this approach is complicated by the large number of different methods for model averaging and the subsequent uncertainty quantification of averaged predictions. Several previous reviews on model averaging in ecology and evolution focused exclusively on “information-theoretical model averaging” (Johnson and Omland 2004, Hobbs and Hilborn 2006, Burnham et al. 2011, Freckleton 2011, Grueber et al. 2011, Nakagawa and Freckleton 2011, Richards et al. 2011, Symonds and Moussalli 2011), probably under the influence of the AIC-weighted (Akaike information criterion) averaging popularized by Burnham and Anderson (2002, Posada and Buckley 2004). Bayesian model averaging has been used less frequently in ecology (for an example see Corani and Mignatti 2015), but, for an excellent recent review of this topic in the context of Bayesian model selection, see Hooten and Hobbs (2015, see also Hoeting et al. 1999, Ellison 2004, Link and Barker 2006). However, none of the above covers all available model averaging approaches, together with a general discussion of advantages and disadvantages.

Our aim is to provide such a comprehensive review in the light of developments over the last 20 years, summarizing the mathematical reasoning behind model averaging, and offering an intuitive but technically sound entry to the field, illustrated by case studies. We primarily address prediction averaging of correlative models, although most of the points will similarly apply to mechanistic/process-based models (see, e.g., Diks and Vrugt 2010, Knutti et al. 2010 for reviews in the context of climate and hydrological models, respectively). We do not consider averaging model parameters, because we agree with the criticism summarized in Banner and Higgs (2017): parameters (such as partial regression coefficients) are estimated conditional on the model structure; as the model structure changes, parameters may become incommensurable (see Posada and Buckley 2004, Cade 2015, Banner and Higgs 2017, and Appendix S1.1 for short review of the parameter-averaging literature). Instead, our focus is on prediction, and predictive inference (sensu Geisser 1993), as exemplified by model-averaged predictions of species potential occurrence for reserve-site selection (Meller et al. 2014) or the effect of roads on occupancy of ponds by frogs (Dai and Wang 2011). Also, we only focus on averaging sets of models that differ in structure, as opposed to mere differences in initial conditions or parameter values (Gibbs 1902, Johnson and Bowlar 2009). The latter case is called “ensemble” in the statistical and physical sciences, while in ecology that term is used more loosely.

This review is divided into five parts: first, we present the mathematical logic behind model averaging, and why this alone puts severe constraints on how we do model averaging. Then, in the second part, we review the different ways through which model-averaging weights can be derived, comparing Bayesian, information-theoretic, and tactical perspectives (by tactical we mean heuristic approaches to model averaging that are not explicitly based on statistical theory). This is followed by a brief exploration of how to quantify the uncertainty of model-averaged predictions. Finally, we briefly illustrate model averaging with two case studies, before closing with unresolved challenges, and recommendations.

The Mathematics Behind Model Averaging

In accordance with virtually all discussions of model averaging we encountered, we first focus on how model averaging reduces prediction error, here quantified as mean squared error (MSE) of a prediction $\hat{Y}_m$ of model $m$. As for any estimator, we can decompose this error into contributions of bias and variance:

$$\text{MSE}(\hat{Y}_m) = \text{bias}(\hat{Y}_m)^2 + \text{var}(\hat{Y}_m).$$

(1)

Bias refers to a systematic model error that would not change if a new data set for the same system became available, while variance refers to the expected spread of model predictions when fit with hypothetical new data sets for the same system.

We can use Eq. 1 to examine the error of a weighted average $\bar{Y}$ of the predictions of several ($M$) contributing models, $\hat{Y}_1, \hat{Y}_2, \ldots, \hat{Y}_M$

$$\bar{Y} = \frac{\sum_{m=1}^{M} w_m \hat{Y}_m}{\sum_{m=1}^{M} w_m}, \quad \text{with} \sum_{m=1}^{M} w_m = 1.$$

(2)

The motivation for the weights $w_m$ is to adjust the average such that is has improved properties over a simple average (with equal weights) or a single candidate models (all weight on one model).

We can see from Eq. 1 that bias, i.e., the difference between the expectation of the averaged predictions and the truth ($\bar{Y} - y^*$), will depend directly on the bias of the contributing models, as well as their weights (Eq. 2). The
statistical model-averaging literature often assumes that individual models have no bias, and therefore tends to be less interested in its contribution (Bates and Granger 1969, Buckland et al. 1997, Burnham and Anderson 2002). In contrast, for process models, reducing bias is often named as one of the main motivations for model averaging (e.g., Solomon et al. 2007, Gibbons et al. 2008, Dietze 2017). Implicitly, the assumption here is that model biases will tend to fall on both sides of the truth, in which case they may cancel out in an average.

Prediction variance (arising from \(n\) hypothetical repeated samplings) is composed of two terms, the variance of each contributing model’s prediction

\[
\text{var}(\hat{Y}_m) = \frac{1}{n-1} \sum_{i=1}^{n} (\overline{Y}_m - \hat{Y}_m)^2
\]

and the covariances between predictions of model \(m\) and \(m'\)

\[
\text{cov}(\hat{Y}_m, \hat{Y}_{m'}) = \frac{1}{n-1} \sum_{i=1}^{n} (\overline{Y}_m - \hat{Y}_m)(\overline{Y}_{m'} - \hat{Y}_{m'})
\]

For the average of two predictions, \(\hat{Y}_1\) and \(\hat{Y}_2\), this yields

\[
\text{var}(\hat{Y}) = w_1^2 \text{var}(\hat{Y}_1) + w_2^2 \text{var}(\hat{Y}_2) + 2w_1w_2 \text{cov}(\hat{Y}_1, \hat{Y}_2) \tag{3}
\]

When averaging several models, we expand Eq. 3 to

\[
\text{var}(\hat{\bar{Y}}) = \text{var}\left(\sum_{m=1}^{M} w_m \hat{Y}_m\right) = \sum_{m=1}^{M} w_m^2 \text{var}(\hat{Y}_m)
\]

\[+ \sum_{m=1}^{M} \sum_{m'=1, m' \neq m}^{M} w_m w_{m'} \text{cov}(\hat{Y}_m, \hat{Y}_{m'})\]

\[= \sum_{m=1}^{M} \sum_{m'=1, m' \neq m}^{M} w_m w_{m'} \rho_{mm'} \sigma(\hat{Y}_m) \sigma(\hat{Y}_{m'}) \tag{4}\]

where \(\rho_{mm'}\) is the correlation between \(\hat{Y}_m\) and \(\hat{Y}_{m'}\), and \(\sigma(.)\) is their standard deviation.

Combining Eqs. 1 and 3 we can see that the error of a model-averaged prediction decomposes into

\[
\text{MSE}(\hat{\bar{Y}}) = \left(\sum_{m=1}^{M} w_m (E(\hat{Y}_m) - y^*)\right)^2
\]

\[+ \sum_{m=1}^{M} \sum_{m'=1, m' \neq m}^{M} w_m w_{m'} \rho_{mm'} \sigma(\hat{Y}_m) \sigma(\hat{Y}_{m'})\]

where \(E(\hat{Y}_m) - y^* = \text{bias}(\hat{Y}_m)\) represents prediction bias.

**Fig. 1.** Conceptual depiction of the contributions of error to model averaging. (A) Contributing models have larger bias than variance. The error of the average depends on how the bias is averaged out. It can increase or decrease compared to the best model. Adding a lot more models will not change the error, unless this reduces bias. (B) Contributing models have similar bias and variance. In this case, averaging an increasing number of models can reduce the variance of the error, while the bias remains. (C) Contributing models are unbiased, but have large variance. In this case (assuming covariances between models are low), an increasing number of models can, in principle, make the error arbitrarily small.
To understand what influences the error of model-averaged predictions

Eq. 5 allows us to make a number of statements about the potential benefits of model averaging. We shall first illustrate the fundamental effects of bias, variance, and covariance using simple toy examples. In the next sections, we shall then move from this idealized examples to more realistic situations.

First, when each model produces a distinct prediction, with variances substantially lower than systematic differences between models, bias dominates (Fig. 1 top). How useful model averaging is in this situation depends on the biases of the individual models (see also Fig. 2 top row). As model variance increases (or bias decreases), the error term is increasingly dominated by variance, and assuming covariances are low, the variance of the average (and therefore the mean error) will be smaller than the variance of the single model (Fig. 1 bottom). If the covariance of model predictions is low, increasing the number of models in the average will generally decrease the variance and therefore the prediction error, while the bias of the average has no general connection to the number of averaged models (Fig. 2, right column).

We thus conclude that, as bias becomes large relative to prediction variance, model averaging is less and less likely to be useful for reducing variance – but it may still be useful for reducing bias (under the condition of bidirectional bias: Fig. 2, lower row).

To understand these effects in more detail, consider the unlikely, but didactically important case that model predictions are independent, meaning that their covariance is 0 and the correlation matrix $\rho_{m\to}$ of Eq. 5 becomes the identity matrix (or, equivalently, the covariance term of Eq. 4 vanishes). If we also assume both predictions have equal variances, $\text{var}(\hat{Y}_1) = \text{var}(\hat{Y}_2) = \text{var}(\bar{Y})$, since $w_2 = 1 - w_1$, the above equation simplifies to $\text{var}(\bar{Y}) = (2w_1^2 - 2w_1 + 1)\text{var}(\bar{Y})$. If one model gets all the weight, we have $\text{var}(\bar{Y}) = \text{var}(\bar{Y})$. If the two models receive equal weight, we have $\text{var}(\bar{Y}) = (2 \times 0.5^2 - 2 \times 0.5 + 1)\text{var}(\bar{Y}) = 0.5\text{var}(\bar{Y})$, a considerable improvement in prediction variance (and the minimum of this equation). Other weights fall between these values. In other words, model averaging can reduce prediction error because weights enter as quadratic terms in Eq. 3, rather than linearly. Indeed, Bates and Granger (1969) showed that for unbiased models with uncorrelated predictions, the variance in the average is never greater than the smaller of the individual predictions (making the important assumption that the weights are known, which will be discussed in section Estimating weights can thwart the benefit of model averaging).

The next thing to note is that the correlation between model predictions, i.e., the matrix $(\rho_{ij}) \in \mathbb{R}^{m \times m}$, substantially affects the benefit of model averaging (see also Fig. 3 and interactive tool in Data S1). In the best case, correlations between model predictions are negative or at least absent, and the second term of Eq. 5 is negative or vanishes. Under these conditions, averaging can substantially decrease the variance of the averaged prediction. As correlations between predictions increase, the covariance term contributes more and more to the overall prediction error. In the extreme case of perfectly correlated predictions of the single models, model averaging has no benefit for reducing prediction variance.

The effect of correlations on the potential reduction of prediction error has an analogy in biodiversity studies, where it is called the “portfolio effect” (e.g., Thibaut and Connolly 2013).
Fig. 3. When averaging is optimal, in the simplest case of two models that make correlated Gaussian predictions. The models are here described by their biases \((b_1, b_2; \text{not shown})\), their standard deviations \((\sigma_1, \sigma_2)\), and by the correlation \((\rho)\) between them. Each panel shows the regions in the \((\sigma_1, \rho)\) plane where model 1 is best (blue shading and contour line), model 2 is best (orange shading and contour line), and where the optimal average is best (color gradient between blue and orange). Top row represents the case where weights, \(w\), are known (i.e., without error: \(\sigma_1 = 0\)), while the second row represents exactly the same settings, but with estimated weights (with uncertainty \(\sigma_1 = 0.2\)). Notice that when \(w\) is estimated with uncertainty, the contours marking the transition between each single model and the average move into the washed-out colours, i.e., deviate from the fixed \(w\) situation in the upper panels. These curves now represent a level set at the values \(\tilde{w}_1 = 1 - \sigma_n\) (blue curve) and \(\tilde{w}_2 = \sigma_n\) (orange curve). As a consequence, the area where model averaging with estimated weights is superior to the better single model decreases substantially relative to the fixed \(w\) case, and disappears completely for \(\sigma_n \geq 0.5\). Formal derivations for the contours and the critical weights is given in Appendix S1.2, the interactive tool itself in Data S1. Biases are set to \(b_1 = 3\) and \(b_2 = 2\).

It states that the fluctuation in biomass of a community is less than the fluctuations of biomass of its members, because the species respond to the environment differently. This asynchrony in response is analogous to negative covariance in community members’ biomass, buffering the sum of their biomasses.

This point also provides some important insights about why machine learning methods, which often average a large number of bad models, can work so well. When averaging poor models, e.g., trees in a Random Forest, covariance is negligible, but the variance of each model prediction is high. Because \(\sigma_m\) becomes very small with hundreds of models (approximately \(1/M\)), the variance of many averaged poor models (with similar variance) tends to be low: \[ \text{var}(\tilde{Y}) = \sum_{m=1}^{M} \frac{1}{\sqrt{M}} \text{var}(\tilde{Y}_m) + \frac{1}{\sqrt{M}} \sum_{m=1}^{M} \sum_{n \neq m} \text{cov}(\tilde{Y}_m, \tilde{Y}_n) \approx M \frac{1}{\sqrt{M}} \text{var}(\tilde{Y}) = \frac{1}{\sqrt{M}} \text{var}(\tilde{Y}) , \] where the second term disappears due to lack of correlations among predictions. We may speculate that poor models typically also exhibit substantial but bidirectional bias, which again would be reduced by averaging.

Putting bias, variance and correlation together (Fig. 2), we note that model averaging will deliver smaller prediction error when bias is bidirectional (i.e., model predictions over- and underestimate the true value: bottom row of Fig. 2) and predictions are negatively correlated (Fig. 2 bottom right). Uni-directional bias will remain problematic (top row of Fig. 2), irrespective of covariances among predictions.

Thus, for a given set of weights, the prediction error of model-averaged predictions depends on three things: the bias of the model average, as emerging from the bias of the individual models, the prediction variances of the individual models, and the covariance of those predictions.

**Estimating weights can thwart the benefit of model averaging**

So far, we have assumed that weights have fixed values, and thus there is no uncertainty about them. Yet, the aim of optimizing predictive performance suggests that weights need to be estimated from the data. But estimation brings associated uncertainty with it, and this has implications for the actual benefits of model averaging: estimated “optimal” weights will be suboptimal (Nguefack-Tsague 2014). With such an error, even for only mildly correlated predictions, the averaged prediction will have more variance, and possibly bias, than if the (unknown) truly optimal weights were used (Claeskens et al. 2016). It may, in fact, often be no better than one obtained using arbitrary weights, e.g., equal weights (Clemen 1989, Smith et al. 2009, Graefe et al. 2014, 2015). The “simple theoretical explanation” provided by Claeskens et al. (2016) demonstrates that estimating weights introduces additional variance into the prediction. As a consequence, the predictions averaged with estimated weights may be worse than that of a single model (in contrast to the assertion of Bates and Granger 1969, see Claeskens et al. 2016 for an example).

Apart from the error of the estimate, a further open problem is to obtain a good estimator for the optimal weight in the first place. Currently no closed solution is available, not even for linear models (Liang et al. 2011). Neither Bayesian nor information-theoretical model weights are designed to minimize prediction error, and their weights will in general not be optimal for that purpose. Some tactical approaches estimate model weights explicitly to minimize prediction error on hold-out data (in particular jackknife model averaging and stacking; see Tactical approaches to computing...
model weights). Only these approaches are at least trying to estimate optimal weights for minimizing predictive error. The interactive tool we provide (Fig. 3) allows readers to explore this issue in a simple two-model case. It shows that, in this simple case, estimating weights substantially reduces the parameter space where model averaging is superior to the best single model. Thus, the bias-variance trade-off applies also to model averaging, in the sense that weight estimation introduces additional parameters and therefore higher model complexity to the analysis. It is therefore important to think carefully about when to use model averaging, as it can add unnecessary complexity.

Uncertainty about the optimal weights does not imply that estimated weights are of no use, or that the use of arbitrary weights (e.g., equal weights) is generally superior. While uncertainty in estimated weights increases prediction error, the ability to statistically downweight or wholly remove unsuitable models from the prediction set is a substantial benefit. In Claeskens et al. (2016) and similar simulations, all models considered are “alright” (bias-free and with similar prediction variance), which obviously need not be the case in practical applications. Thus, the question is not if estimated model weights are useful in general, but how useful they are beyond their function of filtering out inferior models from the average. We believe there is a benefit beyond this filter function, but we recognize that there is a need for further research to better demonstrate this benefit, and understand when it occurs.

Model averaging (typically) reduces prediction errors

To complement these theoretical considerations, we examined 180 studies (a random draws from the results of a systematic literature search: see Appendix S1.7) regarding reported benefits from model averaging.

The majority of studies we encountered used an empirical approach to assess predictive performance, i.e., forecasting, hindcasting, or cross-validation to observed data (e.g., Namata et al. 2008, Marmion et al. 2009a,b, Grenouillet et al. 2010, Montgomery et al. 2012, Engler et al. 2013, Smith et al. 2013, Edeling et al. 2014, Trolle et al. 2014). Model averaging typically yielded lower prediction errors than the individual contributing models. Most of these studies used test data sets to estimate predictive success, and rely critically on the assumption of independence between test and training data sets (Roberts et al. 2017). Few studies used simulated data to examine the performance of model averaging under specific conditions (e.g., small sample size, model structure uncertainty, missing data; Ghosh and Yuan 2009, Schomaker 2010), and even fewer employ analytical mathematics (Shen and Huang 2006, Potempski and Galmarini 2009, Chen et al. 2012, Zhang et al. 2013).

Quantifying uncertainty of model-averaged predictions

So far, we have shown that model averaging can produce predictions with a smaller error than any of the contributing models by averaging away their variance and bias. Those gains, however, generally decrease with increasing covariance of the individual model predictions, and increasing mean bias of the contributing models. Moreover, weighted averaging allows reducing the weight of models poorly supported by data, but at the expense of introducing additional variance in the average, induced by the weight estimation.

Besides having an estimate with low error, the second goal of most statistical methods is to provide a measure of (un)certainty of that estimate. The nature of this measure differs between tactical, Bayesian, and frequentist approaches. Tactical approaches, such as machine learning, are usually satisfied with providing an estimate of predictive error on new data, typically obtained through cross-validation. This procedure can be directly extended to model-averaged predictions.

For Bayesian and frequentist methods, the issue of extending the conventional methods for estimating uncertainty to model-averaging is somewhat more complicated. Bayesian methods quantify uncertainty via the posterior distribution, which can be summarized by a Bayesian credible interval. One would interpret a 95% credible interval as displaying a 95% certainty for the true value to be contained in the interval. Frequentist methods traditionally provide a confidence interval. Under repeated sampling of new data sets under identical conditions, a correctly defined 95% confidence interval should contain the true value in 95% of the cases.

To construct a frequentist confidence interval for a model-averaged prediction, we have to ask ourselves how this model-averaged prediction will spread around the true value under repeated sampling. Fortunately, we have already derived this result in Eqs. 1–5. For simple cases, we can directly convert this into a confidence interval. For example, for an unbiased average, with uncorrelated models of equal weight and variance, the standard deviation of the average, and thus its confidence interval, should decrease with one over the square root of the number of contributing models, times the confidence interval of the single models. In general, however, the calculation of the confidence interval of the average will have to take the confidence intervals of all contributing models, as well as their weights, covariance and bias into account.

Buckland et al. (1997) proposed a simplification of Eq. 5, which considers bias and variance of the averaged models (for derivation see Burnham and Anderson 2002:159–162)

\[
\text{var}(\hat{Y}) = \left( \sum_{m=1}^{M} w_m \sqrt{\text{var}(\hat{Y}_m) + \gamma_m^2} \right)^2
\]

(6)

Mis specification bias of model \(m\) is computed as \(\gamma_m = \hat{Y}_m - \hat{Y}\), thus assuming (explicitly on page 604 of of Buckland et al. 1997) that the averaged point estimate \(\hat{Y}\) is unbiased and can hence be used to compute the bias of the individual predictions. This assumption can be visualized in Fig. 2 as the situation where the empty triangles always sit right on top of “truth.” This assumption is problematic, as it cannot be met by unidirectionally biased model predictions, nor when weights \(w_m\) fail to get the weighting exactly right and thus \(\hat{Y}\) remains biased. Less problematically, Buckland et al. (1997) also assumed that predictions from different models are perfectly correlated, making the covariance term as large as possible, and variance estimation conservative. The distribution theory behind this approach has been criticized as “not (even approximately) correct” (Claeskens and Hjort 2008:207), but shown to work well in simulations (Lukacs et al. 2010, Fletcher and Dillingham 2011).

Improving on Eq. 6 requires knowledge of the correlation of model predictions \(\rho_{mm}\) (Eq. 5). The key problem is that there
is no analytical way to compute $\mathcal{P}_{\text{opt}}$. Bootstrapping, although computationally costly, offers a good solution to this problem.

While the obstacles to calculate confidence intervals for model-averaged predictions may seem somewhat discouraging, it should be noted that alternatives to model averaging do not necessarily fare better. Predictions from a selected single-best model are underestimates, e.g., the true prediction error (e.g., Namata et al. 2008, Fletcher and Turek 2012, Turek and Fletcher 2012). The reason is that the uncertainty about which model is correct is not included in this final prediction: we predict as if we had not carried out model selection but had known from the beginning which model would be the best (as if the model had been “prescribed”: Harrell 2001). Thus, even if we were able to choose, from our model set $M$, the model closest to truth, we would still need to adjust the confidence distribution for model selection; and a perfect adjustment was analytically shown not to exist (Kabaila et al. 2015).

Accordingly, simulation studies have suggested that model averaging may improve coverage (Wintle et al. 2003, Namata et al. 2008, Zhao et al. 2013), presumably because the process of averaging allows us to take into account model uncertainty (Liang et al. 2011). Yet, given the diversity of approaches to computing model weights encountered in Approaches to Estimating Model-Averaging Weight, these studies cannot be seen as conclusive, only as suggestive, for the improvement of nominal coverage using model averaging. For example Fletcher and Turek (2012) and Turek and Fletcher (2012) explore how model averaging can improve the tail areas of the confidence distribution. These two studies, however, as well as those cited before, assumed that the full model, referring to the model that includes all sub-models prior to any model selection (see Appendix S1.3), is not in the set. The approach by Fletcher and Turek (2012) was re-analyzed by Kabaila et al. (2015). The key finding of this latter study is that the full model coverage was still superior to all other model averaging approaches, suggesting that the full model should currently be kept in mind, both for inference, minimal bias and correct prediction intervals (see also Harrell 2001:59). Such findings sit uncomfortably with the bias–variance trade-off (Hastie et al. 2009), which states that overly complex models have poor predictive performance; and indeed the full model has high prediction variance.

Regrettably, such reasoning cannot be extended in an obvious way to non-nested models, process models, or machine learning models. Here, model averaging seems without alternative for propagating model selection uncertainty into prediction uncertainty more fairly.

Our final option to quantify uncertainty, the Bayesian credible interval, can be interpreted as a mixture distribution. In a two-step process, the model weights first determine the probability of any model to be correct, and the uncertainty of each model is then mixed additively into a averaged uncertainty. If the predictions of all individual models are identical, the final distribution will remain the same; from the perspective of Eq. 5, this is identical to assuming that the average models are perfectly correlated, although the logical motivation for the mixing is different. If predictions differ widely, e.g., due to bias, the mixed confidence distribution will be much wider and possibly multi-modal.

To illustrate the various Bayesian and frequentist options, we calculated predictive uncertainties and coverage for four different options for a set of simple linear regressions in Fig. 4:

1) Make the assumption that model-averaged predictions are unbiased. Use bootstrapping to estimate covariances of predictions for each model. From these estimates, compute prediction variance according to Eq. 5. This solution is computer-intensive, but it takes into account covariance of model predictions. On the other hand, it cannot account for bias, and should thus not be used when bias of the estimator is suspected, for example from cross-validation.

2) Make the assumption that model-averaged predictions are unbiased. Use Buckland et al. (1997)’s approach (Eq. 6). This will yield wider estimates than option 1, because assumptions about bias and correlation are more conservative.

3) Use a mixture distribution to compute the confidence distribution of the average, assuming effectively that predictions from different models are perfectly correlated, but possibly biased.

4) Fit the full model (if available) and use its confidence distribution, which can rarely be improved on (Kabaila et al. 2015).

When averaging models with largely independent (i.e., uncorrelated) predictions, only the bootstrap-estimated covariance matrix (option 1 above) will also compute lower variances (according to Eq. 4). In our example (Fig. 4, see Data S1 for details), “propagation” produced the tightest confidence interval (and hence lowest coverage), followed by “Buckland” and “mixing”. However, neither of these confidence intervals seemed large enough, as all had too low coverage (suggesting model bias to be relevant in this example). Only the full model produces accurate confidence intervals and coverage. Further simulations along these lines will have to show how these approaches perform for more complex models and situations.

**Approaches to Estimating Model-Averaging Weights**

So far, we have discussed the properties of a weighted model average, but we have not discussed how to estimate the model-averaging weights. Estimating weights aims at abating poorly fitting, and elevating well-predicting models, and the actual method for estimating weights has obvious fundamental importance for the quality of an averaged prediction. Different perspectives on model-averaging weights have emerged (Table 1), which can be broadly classified into four categories of decreasing probabilistic interpretability:

1) In the Bayesian perspective, model weights are probabilities that model $M$ is the “true” model (e.g., Link and Barker 2006, Congdon 2007).

2) In the information-theoretic framework, model weights are measures of how closely the proposed models approximate the true model as measured by the Kullback–Leibler divergence, relative to other models.

3) In a “tactical” perspective, model weights are parameters to be chosen in such a way as to achieve best predictive performance of the average. No specific interpretation of the model is attached to the weights; they only have to work.
4) Assigning fixed, equal weights to all predictions can be seen as a reference naïve approach, representing the situation without adjusting for differences in models’ predictive abilities. We shall address these four perspectives in turn, also hinting at relationships among them.

Bayesian model weights

Theory.—Bayes’ formula can be applied to choosing among models in much the same way as to parameter values (Wasserman 2000). To perform inference with multiple models and their parameters at the same time, one can write down the joint posterior probability \( P(M_i, \Theta_i | D) \) of model \( M_i \) with parameter vector \( \Theta_i \), given the observed data \( D \), as

\[
P(M_i, \Theta_i | D) \propto L(D|M_i, \Theta_i) \times p(\Theta_i) \times p(M_i),
\]

where \( L(D|M_i, \Theta_i) \) is the likelihood of model \( M_i \), \( p(\Theta_i) \) is the prior distribution of the parameters of the respective model \( M_i \), and \( p(M_i) \) is the prior weight on model \( M_i \).

In practice, one is often interested in some simplified statistics from this distribution, such as the model with the highest posterior model probability, or the distribution of a prediction including model selection uncertainty. To obtain this information, we can marginalize (i.e., integrate) over parameter space, or marginalize over model space, respectively.

If we marginalize over parameter space, we obtain posterior model weights that represent the relative probability of each model (whilst marginalizing over model space yields averaged parameters, which we shall not address here). We can calculate these weights as the marginal likelihood of each model, defined as the average of Eq. 7 across all \( k \) parameters for any given model

\[
P(D|M_i) \propto \int_{\Theta_1} \cdots \int_{\Theta_k} L(D|M_i, \Theta_i)p(\Theta_i)d\Theta_1 \cdots d\Theta_k.
\]

From the marginal likelihood, we can compare models via the Bayes factor, defined as the ratio of their marginal likelihoods (e.g., Kass and Raftery 1995)

\[
BF_{ij} = \frac{P(D|M_i)}{P(D|M_j)} = \frac{\int L(D|M_i, \Theta_i)p(\Theta_i)d\Theta_i}{\int L(D|M_j, \Theta_j)p(\Theta_j)d\Theta_j},
\]

with the multiple integral now pulled together for notational convenience. For more than two models, however, it is more useful to standardize this quantity across all models in question, calculating a Bayesian posterior model weight \( p(M_i | D) \) (including model priors \( p(M_i) \) : Kass and Raftery 1995) as

\[
\text{posterior model weight}_i = \frac{P(D|M_i)p(M_i)}{\sum_j P(D|M_j)p(M_j)}.
\]

Notes: AIC, Akaike information criterion; WAIC, widely applicable information criterion; BIC, Bayesian information criterion.

†Does this method require a maximum-likelihood fit and/or number of parameters (pm) of the model? Typically these two are linked, since maximum-likelihood approaches typically employ the general linear model (GLM), which provides both information.

‡See also Appendix for details and case studies in Data SI for examples of implementation in R.

§While nonparametric models have no readily extractable number of parameters, a Generalized Degrees of Freedom-approach could be used to compute them (Ye 1998). Similarly, but more efficiently, cross-validation can be used to estimate the effective number of parameters (Hauenstein et al. 2017).

#Implemented in MuMIn as part of this publication.

Estimation in practice.—While the definition of Bayesian model weights and averaged parameters is straightforward, the estimation of these quantities can be challenging. In practice, there are two options to numerically estimate the quantities defined above, both with caveats.

The first option is to sample directly from the joint posterior (Eq. 7) of the models and the parameters. Basic algorithms such as rejection sampling can do that without any modification (e.g., Toni et al. 2009), but they are inefficient for higher-dimensional parameter spaces. More sophisticated algorithms such as MCMC and SMC (see Hartig et al. 2011, for a basic review) require modifications to deal with the issue of different number of parameters when changing between models. Such modifications (mostly the reversible-jump MCMCs, rjMCMC; Green 1995; see Appendix S1.5.1) are often difficult to program, tune and generalize, which is the reason why they are typically only applied in specialized, well-defined settings. The posterior model probabilities of the rjMCMC are estimated as the proportion of time the algorithm spent with each model, measured as the number of iterations the algorithm drew a particular model divided by the total number of iterations.

The second option is to approximate the marginal likelihood in Eq. 8 of each model independently, renormalize that into weights, and then average predictions based on these weights. The challenge here is to get a stable approximation of the marginal likelihood, which can be problematic (Weinberg 2012; see Appendix S1.5.1). Still, because of the relatively simple implementation, this approach is a more common choice than rjMCMC (e.g., Brandon and Wade 2006).

Influence of priors.—A problem for the computation of model weights when performing Bayesian inference across multiple models is the influence of the choice of parameter priors, especially “uninformative” ones (see Chickering and Heckerman 1995, Hoeting et al. 1999: section 5).

The challenge arises because in Eqs. 8 and 9 the prior density p(θi) enters the marginal likelihood, and hence the Bayes factor, multiplicatively. This has the somewhat unintuitive consequence that increasing the width of an uninformative parameter prior will linearly decrease the model’s marginal likelihood (e.g., Link and Barker 2006). That Bayesian model weights are strongly dependent on the width of the prior choice has sparked discussion of the appropriateness of this approach in situations with uninformative priors. For example, in situations where multiple nested models are compared, the width of the uninformative prior may completely determine the complexity of models that are being selected. One suggestion that has been made is to not at all perform multi-model inference with uninformative priors, but at least additional corrections are necessary to apply Bayes factors weights (O’Hagan 1995, Berger and Pericchi 1996). One such correction is to calibrate the model on a part of the data first, use the result as new priors and then perform the analysis described above (intrinsic Bayes factor: Berger and Pericchi 1996, fractional Bayes factor: O’Hagan 1995). If enough data are available so that the likelihood is
sufficiently peaked by the calibration step, this approach should eliminate any complication resulting from the prior choice (for an ecological example see van Oijen et al. 2013).

**Bayesian-flavoured approaches.**—Apart from the natural Bayesian average (see also Yao et al. 2017), there are a number of other approaches that are connected to or inspired by Bayesian thinking.

In a set of influential publications, Raftery et al. (1997), Hoeting et al. (1999), and Raftery et al. (2005) introduced post hoc Bayesian model averaging, i.e., for vectors of predictions from already fitted models. The key idea is to iteratively estimate the proportion of times a model would yield the highest likelihood within the set of models (through expectation maximization, see Appendix S1.5.2 for details), and use this proportion as model weight. In the spirit of the inventors, we refer to this approach as Bayesian model averaging using Expectation-Maximization (BMA-EM), but place it closer to a frequentist than a Bayesian approach, as the models were not necessarily (and in none of their examples) fitted within the Bayesian framework. It has been used regularly, often for process models (e.g., Gneiting et al. 2005, Zhang et al. 2009), where an rMCMC procedure would require substantial programming work at little perceived benefit, but also in data-poor situations in the political sciences (Montgomery et al. 2012).

Chickering and Heckerman (1997) investigate approximations of the marginal likelihood in Eq. 9, such as the Bayesian Information Criterion (BIC, defined in the next section; see also Appendix S1.5.3) and find them to work well for model selection, but not for model averaging. In contrast, Kass and Raftery (1995:778) state the eBIC is an acceptable approximation of the Bayes factor, and hence suitable for model averaging, despite being biased even for large sample sizes. These approximations may be improved when using more complex versions of BIC (SPBIC and IBIC; Bollen et al. 2012).

The “widely applicable information criterion” WAIC (Watanabe 2010 and an equivalent WBIC Watanabe 2013) are motivated and actually derived in a Bayesian framework (Gelman et al. 2014). With an uninformative savvy prior, it can be seen as a variation of AIC (see next section). With an uninformative framework (Gelman et al. 2014). With an uninformative framework (Gelman et al. 2014), WAIC is the likelihood of observing the data under the posterior distributions of parameters \( \theta \), corrected by a penalty of \(-2\log(n)\) rather than AIC’s “2” as penalization factor for model complexity (Appendix S1.5.3). A particularly noteworthy modification of the AIC exist, where the model fit is assessed with respect to a focal predictor value, e.g., a specific age or temperature range, yielding the Focussed Information Criterion (FIC; Claeskens and Hjort 2008). We are not aware of a systematic simulation study comparing the performance of these model averaging weights, but AIC’s dominance should not indicate its superiority (see also case study 1 below).

### Information-theoretic model weights

In the information-theoretic perspective, models closer to the data, as measured by the Kullback-Leibler divergence, should receive more weight than those further away.

There are several approximations of the KL-divergence, most famously Akaike’s Information Criterion (AIC; Akaike 1973, Burnham and Anderson 2002). AIC and related indices can be computed only for likelihood-based models with known number of parameters \( (p_m) \), restricting the information-theoretic approach to GLM-like models (including GAM):

\[
AIC_m = -2\ell_m + 2p_m \quad \text{and} \quad w_m = \frac{e^{-0.5(AIC_m - AIC_{min})}}{\sum_{i \in M} e^{-0.5(AIC_i - AIC_{min})}}
\]

where \( \ell_m \) is the log-likelihood of model \( m \).

In the ecological literature, AIC (and its sample-size corrected version AICc, and its adaptations to quasi-likelihood models such as QIC; Pan 2001, Claeskens and Hjort 2008) is by far the most common approach to determine model weights (for recent examples see, e.g., Dwyer et al. 2014, Rovai et al. 2015), despite the fact that the reasoning behind this choice is not entirely clear. AIC-weights (Eq. 11) have been interpreted as Bayesian model probabilities (Burnham and Anderson 2002:75, Link and Barker 2006), assuming a specific, model complexity and sample size-dependent, “savvy prior” (Burnham and Anderson 2002:302, see also Hooten and Hobbs 2015:16, for reformulation as regularization prior). An alternative interpretation is the proportion of times a model would be chosen as the best model under repeated sampling (Hobbs and Hilborn 2006), but such an interpretation is contentious (Richards 2005, Bolker 2008, Claeskens and Hjort 2008). In an anecdotal comparison, Burnham and Anderson (2002:178) showed that AIC weights are substantially different from bootstrapped model weights. The latter were proposed by Buckland et al. (1997) and represent the proportion of bootstraps a model is performing best in terms of AIC: see case study 1 below. In simulations, AIC weights did not reliably identify the model with the known lowest KL-divergence or prediction error (Richards 2005, Richards et al. 2011). Instead, Mallows’ model averaging (MMA) has been shown to yield the lowest mean squared error for linear models (Hansen 2007, Schomaker et al. 2010). Mallows’ \( C_p \) penalizes model complexity equivalent to \(-2\ell_m - n + 2p_m \) (for \( n \) data points; rather than AIC’s \(-2\ell_m + 2p_m \), Eq. 11).

**Schwartz’ Bayesian Information Criterion** was derived to find the most probable model given the data (Schwartz 1978, Shmueli 2010), equivalent to having the largest Bayes factor (see previous section). BIC uses log\( (n) \) rather than AIC’s “2” as penalization factor for model complexity (Appendix S1.5.3). A particularly noteworthy modification of the AIC exist, where the model fit is assessed with respect to a focal predictor value, e.g., a specific age or temperature range, yielding the Focussed Information Criterion (FIC; Claeskens and Hjort 2008). We are not aware of a systematic simulation study comparing the performance of these model averaging weights, but AIC’s dominance should not indicate its superiority (see also case study 1 below).

The weighting procedure can additionally be wrapped into a cross-validation and model pre-selection, which leads to the ARMS-procedure (Adaptive Regression by Mixing with model Screening; Yang 2001, Yuan and Yang 2005, Yuan and Ghosh 2008). We shall not present details on ARMS here (for cross-validation see next section), because we regard model pre-selection as an unresolved issue (see...
Validation-based weighting or validation-based pre-selection of models).

Tactical approaches to computing model weights

Methods covered in this section share the “tactical” goal of choosing weights to optimize prediction (e.g., reduce prediction error), without a specific reference to a statistical theory such as Bayesian inference or information theory.

The most straightforward approach in this area is to make the averaging weight dependent on an estimate of the predictive error of each model, usually obtained by cross-validation. Cross-validation approximates a model’s predictive performance on new data by predicting to a hold-out part of the data (typically between 5 and 20 folds, down to leave-one-out cross-validation, which omits each single data point in turn). The fit to the hold-out can be quantified in different ways. If the data can be reasonably well described by a specific distribution with log-likelihood function $\ell$ (even if the model algorithm itself is non-parametric), the log-likelihood of the data in the $k$ folds can be computed and summed (van der Laan et al. 2004, Wood 2015:36):

$$e_{CV}^m = \sum_{i=1}^k \ell(y_{i|j}, \hat{\theta}_{y_{i|j}}^m)$$

where the index $[-i]$ indicates that the data $y_{i|j}$ in fold $i$ were not used for fitting model $m$ and estimating model parameters $\hat{\theta}_{y_{i|j}}^m$. It can be shown that leave-one-out cross-validation log-likelihood is asymptotically equivalent to AIC and thus KL-distance (Stone1977), albeit at a higher computational cost. Hence, computing model weights $w_{CV}^m$ (Hautenstein et al. 2017)

$$w_{CV}^m = \frac{e_{CV}^m}{\sum_{i \in M} e_{CV}^i}$$

creates a weighting scheme very similar to AIC-weights, which implicitly penalizes overfitting.

Other measures of model fit to the hold-out folds have been used, largely as ad hoc proxies for a likelihood function (e.g., in likelihood-free models): pseudo-R$^2$ (e.g., Nagelkerke 1991, Nakagawa and Schielzeth 2013), area under the ROC curve (AUC: Marmion et al. 2009a, Ordonez and Williams 2013, Hannemann et al. 2015), or True Skill Statistic (Diniz-Filho et al. 2009, Garcia et al. 2012, Engler et al. 2013, Meller et al. 2014). In these cases, weights were computed by substituting $\ell_{CV}$ in Eq. 13 by the respective measure, or given a value of 1/$S$ for a somewhat arbitrarily defined subset of $S$ (out of $M$) models, e.g., those above a threshold considered minimal satisfactory performance (Crossman and Bass 2008, Crimmins et al. 2013, Ordonez and Williams 2013).

Largely ignored by the ecological literature are two other non-parametric approaches to compute model weights: stacking and jackknife model averaging (see Appendix S1.4 for discussion of averaging within machine-learning algorithms). Both are cross-validation based, but unlike simple cross-validation weights, which are based on the performance of each contributing model on hold-out data, stacking and jackknife model averaging explicitly optimize weights to reduce the error of the average on hold-out data.

Stacking (Wolpert 1992, Smyth and Wolpert 1998, Ting and Witten 1999) finds the optimized model weights to reduce prediction error (or maximize likelihood) on a test hold-out of size $H$. This is, for RMSE and likelihood, respectively:

$$\arg \min_{w_m} \left\{ \frac{1}{H} \sum_{i=1}^{H} \left( y_{i|-i} - \sum_{m=1}^{M} w_m \hat{f}(X_i | \hat{\theta}_{y_{i|-i}}^m) \right)^2 \right\}$$

(Hastie et al. 2009) and

$$\arg \min_{w_m} \left\{ \ell \left( y_{i|-i} \sum_{m=1}^{M} w_m \hat{f}(X_i | \hat{\theta}_{y_{i|-i}}^m) \right) \right\}$$

where $\hat{f}(X_i | \hat{\theta}_{y_{i|-i}}^m)$ is the prediction of model $m$, fitted without using data $i$, to data $i$. This procedure is repeated many times, each time yielding a vector of optimized model weights, $w_m$, which are then averaged across repetitions and rescaled to sum to 1. Yao et al. (2017) extend this approach also to Bayesian models to provide a clear prediction-error minimizing goal. Smyth and Wolpert (1998) and Clarke (2003) report stacking to generally outperform the cross-validation approach from two paragraphs earlier, and Bayesian model averaging, respectively (see also in Case Studies and Appendix S5).

In Jackknife Model Averaging (IMA; Hansen and Racine 2012), each data point is omitted in turn from fitting and then predicted to (thus actually a leave-one-out cross-validation rather than a “jackknife”). Then, weights are optimized so as to minimize RMSE (or maximize likelihood) between the observed and the fitted value across all $N$ “jackknife” samples. The optimization function is the same as for stacking, except that $H = N$. Thus, in stacking, weights are optimized once for each run, while for the jackknife only one optimization over all $N$ leave-one-out cross-validations is required (further details and examples with R-code are given in Appendix S1.5.6).

The forecasting (i.e., time predictions) literature (reviewed in Armstrong 2001, Stock and Watson 2001, Timmermann 2006) offers two further approaches. Bates and Granger (1969)’s minimal variance approach attributes more weight to models with low-variance predictions. More precisely, it uses the inverse of the variance-covariance matrix of predictions, $\Sigma^{-1}$, to compute model weights. In the multi-model generalisation (Newbold and Granger 1974) the weights vector $w$ is calculated as:

$$w_{\text{minimal variance}} = (1' \Sigma^{-1} 1)^{-1} 1' \Sigma^{-1},$$

where 1 is an $M$-length vector of ones. This is the analytical solution of Eq. 5, assuming no bias and ignoring the problem that weights are random variates, under the weights-sum-to-one constraint. Eq. 14 does not ensure all-positive weights, nor is it obvious how to estimate $\Sigma$. One option (used in our case studies) is to base $\Sigma$ on the deviation from a prediction to test data in lieu of measure of past performance (following recommendation of Bates and Granger 1969).

Finally, Garthwaite and Mubwandarikwa (2010) devised a rarely used method, called the “cos-squared weighting scheme,” designed to adjust for correlation in predictions by different models. It was motivated by (1) giving lower weight
to models highly correlated with others (thereby reducing
the prediction variance contributed through covariances in
Eq. 5), (2) division of weights when a new, near-identical
model prediction is added to the set, and (3) reducing all
weights when more models are added to the set. Weights are
computed as proportional to the amount of rotation the pre-
dictions would require to make them orthogonal in predic-
tion space, hence the trigonometric name of their approach.

Modelling model weights.—So far, weights were always con-
stant. However, one might also consider making weights
dependent on other variables. This approach, which we term
“model-based model combinations” (MBMC, also called
“superensemble modeling”) was first proposed by Granger
and Ramanathan (1984). Here a statistical model \( f \) is used to
combine the predictions from different models, as if they
were predictors in a regression: \( \hat{Y} \sim f(\hat{Y}_1, \hat{Y}_2, \ldots, \hat{Y}_n) \) (see
Fig. 5A). The regression-type model \( f \) can be of any type,
such as a linear model or a neural network. We call this
regression the “supra-model” in order to distinguish
between different modelling levels.

A very simple supra-model would compute the median of
predictions for each point \( X_i \) (e.g., Marmion et al. 2009a).
Different models are used in the “average” without requiring
any additional parameter estimation. Median predictions
imply varying weights, as the one or two models considered
for computing the median may change between different \( X_i \).

An ideal model combination could switch, or gently tran-
sition, between models (such as manually constructed by
Crisci et al. 2017). Since the predictions are combined more
or less freely in model-based model combinations to yield
the best possible fit to the observed data, MBMC should be
superior to any constant-weight-per-model approach (see
Fig. 5B), as was indeed found by Diks and Vrugt (2010).

This advantage comes with a severe drawback: a high pro-
livity to overfitting, as we fit the same data twice (once to
each model, then again to their prediction regression).

This does not seem to be widely recognized as a problem
(despite being a key message of Hastie et al. 2009), as most
studies we found incorrectly cross-validate the supra-model
only, not the entire workflow (if at all; e.g., Krishnamurti et al.
1999, Thomson et al. 2006, Diks and Vrugt 2010, Romero
et al. 2016; but see Breiner et al. 2015). To correctly cross-vali-
date MBMCs, one has to produce hold-outs before fitting the
contributing models, and evaluate the MBMC prediction on
this hold-out (Fig. 5, Appendix S5.9 and case studies; Breiner
et al. 2015). [Correction added 9 July 2018 after online publi-
cation. The work of Breiner et al. (2015) was erroneously
included in the list of studies. This error was due to a misun-
derstanding of the method section in their publication.]

Note that supra-models may differ substantially in their
ability to harness the contributing models. As it is a yet
fairly unexplored field in model averaging, analysts are
advised to try different supra-model types (Fig. 5).

Equal weights

Last, we discuss the most trivial weighting scheme: in
many fields of science (climate modelling, economics, politi-
cal sciences), model averaging proceeds with giving the
structurally different models equal weight, i.e., \( 1/M \) (John-
son and Bowler 2009, Knutti et al. 2010, Graefe et al. 2014,
Rougier 2016). In ecology, studies analyzing species distribu-
tions reported equal weights to be a very good choice when
assessed using cross-validation (Crossman and Bass 2008,
Marmion et al. 2009a, Rapacciuolo et al. 2012), but no bet-
ter than the single models on validation with independent
data (Crimmins et al. 2013). Equal weights may serve as a

Fig. 5. A simple model-based model combination (MBMC) example. (A) Three models (solid grey lines: constant, linear, and quadratic)
fitted separately to a data set (points, following the thin black line). Using a linear model (with quadratic terms: red) to combine the three mod-
els’ its may improve it, even more so than the full model (green), and with narrower confidence intervals. Dotted lines indicate the weight
that each model receives at each point in the linear model. Such MBMC did not necessarily improve fit, as Random Forest-based model combina-
tions showed (blue). (B) Using fivefold cross-validation around the entire workflow shows that the linear supra-model (Supra-LM) indeed
improved prediction (decreased root mean squared prediction error), while the Random Forest-supra-model (Supra-rF) did not. The full
model (as reference) comprised all terms present in Supra-LM, but was fitted directly. Boxes are 50% quantiles, and whiskers are min/max
values (unless those exceed the 50% quantiles by 1.5 the interquartile range); the median is indicated by the horizontal black line.
reference approach to see whether estimating weights reduces prediction error for this specific set of models. In that sense, we may argue, all the above weight estimation approaches only serve to separate the wheat from the chaff; once a set of reasonable models has been identified, equal weights are apparently a good approach.

**Case Studies**

All methods discussed above can be applied to simple regression models, while some explicitly rely on a model’s likelihood and can thus not be used for non-parametric approaches. We therefore devised two case studies, the first being a rather simple example to illustrate the use of all methods in Table 1, and the second a more complicated species distribution case study based on a reduced set of methods. Note that we do not include adaptive regression by mixing (ARM; Yang 2001) because its more sophisticated variations (Yuan and Yang 2005) are not readily implemented in R, and the basic ARMS is barely different from AIC model averaging for a preselected set of models.

**Case study 1: Simulation with Gaussian response, many models and few data points**

In this first, simulation-based case study, we explore the variability of model-averaging approaches in the common case where several partially nested models are fit (see Data S1 for details and code). The simulation was set up so that several of the fitted models have similar support as explanations for the data. This was achieved by generating the response differently in each of two groups (using similar, but not identical predictors). We simulated 70 data points with 4 predictors yielding $2^4 = 16$ candidate models, and another 70 data points for validation. We computed model weights in 19 different ways (Table 1) and compared the prediction error of weighted averages, as well as of the individual models to the validation data points. Simulation and analyses were repeated 100 times.

Two results emerged from this simulation that are worth reporting. First, prediction error (quantified as RMSE) was similar across the 19 weight-computing approaches, with a few noticeably poor exceptions (the two MBMC approaches, minimal variance and the cos-squared scheme; Fig. 6), and most were no better than those of the best nine single model predictions. Second, most averaging approaches gave some weight ($w > 0.01$) to 10 or more models (Table 2), despite models being overlapping and partially nested, so that we have actually only five (more or less) independent models (those containing only one predictor: m2, m3, m5, m9 and intercept-only m1). In real data sets, such spreading of weight is the result of data sparseness or extreme noise, making important effects stand out less; indeed, half of our candidate models are not hugely different, i.e., within $\Delta AIC < 4$.

**Case study 2: Real species presence–absence data, many data points and a moderate number of predictors**

In the second case study, we use data on the real distribution of short-finned eel (Anguilla australis) in New Zealand (from Elith et al. 2008). The data are provided in the R package dismo, already split into a 1000-row training and a 500-row test data set, and featuring 10 predictors. We ran four different model types (GAM, Random Forest [RF], artificial neural network [ANN], support vector machine [SVM]) using all 10 predictors, along with two variations of the GLM (best models selected by AIC and BIC from the full model containing the 10 predictors, relevant quadratic terms and all first-order interactions). For details, see Data S1.

The number of averaging approaches that can be used to compute model weights is smaller than in the previous case study, as three of the six models do not report a likelihood or the number of parameters, precluding the use of rjMCMC, Bayes factor, (W)AIC, BIC, and Mallows’ Cp. Because we do not know the underlying data-generating model, we evaluate the models on the randomly pre-selected test data provided.

One interesting result is that model averaging was effectively a model selection tool in several cases (Table 3). Stacking, bootstrapping, JMA, and to a lesser degree minimal variance, BMA-EM, and the model-based model combinations yielded non-zero weights for only one (or two) models. Apparently, these approaches yielded suboptimal

![Fig. 6. Prediction error of different model averaging approaches (100 repetitions) for case study 1. Box represents quartiles, white line the median. Approaches to the left of the vertical line are very similar, and no better than nine of the candidate models. See Table 1 for list of approaches, and case study 1 in Data S1 for list and its of the individual models.](image-url)
Table 2. Model weights (averaged across 100 repetitions) given to the 16 linear regression models of case study 1 by different weighting methods (see Table 1 for abbreviations), arranged by increasing prediction error (last column, median across replications).

†Weights not available, as different models contribute to the median at each replication.
‡Prediction from individual model.
§Weights are variable. Asterisk indicates that a model’s prediction was a significant term in the supra-model. GAM, rF and GLM refer to
three different types of supra-model: a generalized additive model, a Random Forest, and a generalized linear model.

model weights, as these “model selection” outcomes of model averaging fared worse than those that kept all models in the set (equal weight, leave-one-out, and cos-squared).

Second, the best two model averaging algorithms in this case study, apart from the median where varying weights are used, identified an approximately equal weighting as
optimal strategy. That is somewhat surprising, given that SVM performed relatively poorly (and was excluded by BMA-EM, but favored by cos-squared as a more independent contribution). The likely reason of high weights for the poor SVM is that averaging in less correlated predictions reduces covariances in Eq. 5.

The good performance of the median in both case studies suggests that using the central value of each prediction, rather than give constant weights to the model itself, may be even more effective in reducing variance and thus prediction error. Further research is needed to clarify if this principle is indeed valid across many applications.

**Recommendations**

In this review, we have firstly explained the mechanisms by which model averaging can improve model predictions and, second, we have discussed the large diversity of methods that are available to compute averaging weights. While our general results and outlook on this field are positive, in the sense that model averaging is often useful, the complexity of the topic prevents us from providing final answers about the best approach for ecologists. Surprisingly many issues seem to be statistically unresolved, or addressed by quick fixes and even fundamental questions remain open, which we will discuss next. It is unsatisfactory to see the large variance in weights and performance of the different averaging approaches in our case studies, but also the literature provides too few comparisons of model weights to provide robust advice. In general, our recommendations are thus guided by reducing harm, rather than suggesting an optimal solution.

**Averaged prediction should be accompanied by uncertainty estimates**

Just like any other statistical approach, model averaging can be used wrongly. Focusing entirely on the predictions, rather than their uncertainty, can be misleading, Knutti et al. (2010) showed this for combining precipitation predictions: spatial heterogeneity cancelled out across models, giving the erroneous impression of little change when in fact all models predict large changes (albeit in different regions). Similarly, King et al. (2008) found that averaging parameters from two competing models led to no effect of two hypothesized impacts, although in both models a (different) driver was very influential. We thus strongly encourage including at least model-averaged confidence intervals alongside any prediction, possibly in addition to the individual model predictions, to prevent erroneous interpretation of averaged predictions. Also, more attention should be paid to the full model. It has many desirable properties (unbiased parameter estimates, very good coverage), but suffers from violation of the parsimony principle (“Occam’s razor”) and requires more consideration in which form covariates should be fit. Its larger prediction error, compared to the over-optimistic single-best partial model, is the reason for correct confidence intervals.

**Dependencies among model predictions should be addressed**

Statistical models, which aim to describe the data to which they are fitted, will often have correlated parameters and fits; process models may overlap in modelled processes. Having highly similar models in the model set will inflate the cumulative weight given to them (as illustrated in Appendix S1.6). One way to handle inflation of weights by highly related models is to assign prior model probabilities in a Bayesian framework. Another approach would be to pre-select models of different types (see next point). Alternatively, the cos-square scheme of Garthwaite and Mubwandarikwa (2010) uses the correlation matrix of model projections to appropriately change weights of correlated models. Of the weighting schemes considered here, it is the only approach doing so, but it should be noted that the performance of this approach in our case study was rather poor (Fig. 6, Tables 2 and 3).

**Validation-based weighting or validation-based pre-selection of models**

Madigan and Raftery (1994), Draper (1995), Burnham and Anderson (2002), and more recently Yuan and Yang (2005) and Ghosh and Yuan (2009), have argued that only “good” models should be averaged. Different ways of combining model averaging with a model screening step have been proposed (Augustin et al. 2005, Yuan and Yang 2005, Ghosh and Yuan 2009), in which model selection precedes averaging (pre-selection). This will happen implicitly, and in a single step, if any of the model weight algorithms discussed above attributes a weight of effectively zero to a model, as happened in case study 2. How prevalent this effect is in real world studies is unclear, as weights are rarely reported.

In contrast, some studies select models after the predictions are made (e.g., Thuiller 2004, Forester et al. 2013). These studies have averaged either models that predict in the same direction (along the “consensus axis”; Grenouillet et al. 2010), or the best 50% in the set (Marmion et al. 2009a), or however many models one should combine to minimize prediction error. Such approaches necessitate addressing the challenge of using data twice (Lauzeral et al. 2015). Post-selection reduces the ability of “dissenting voices” (i.e., less correlated predictions) to reduce prediction error and instead reinforce the trend of emphasizing the model type most represented in the set. As a consequence, their uncertainty estimation will be overly optimistic. We do not advocate their use.

We suggest to employ validation-based methods of model averaging rather than relying on model-based estimates of error. That is, we recommend (leave-one out) cross-validation and stacking rather than AIC (in line with recommendations of Hooten and Hobbs 2015). Using (semi-) independent test data gives us some capacity to estimate predictive bias. In such a setting, it may be less relevant whether models are pre-selected by validation-based estimates of error and then averaged with equal weights or weighted by validation-based estimates of error without pre-selection. For this to work, however, it is crucial that (cross)-validation strategies are designed to ensure independence of the validation data, which is a non-trivial problem in many practical ecological applications (Roberts et al. 2017).

**Process models are no different**

In fishery science, averaging process models is relatively common (Brodziak and Piner 2010), as it is in weather and
climate science (Krishnamurti et al. 1999, Knutti et al. 2010, Bauer et al. 2015). There are at least two connected challenges such enterprises face: validation and weighting. Often process models are tuned/calibrated on all sets of data available, in the sensible attempt to describe all relevant processes in the best possible way. That means, however, that no independent validation data are available, so that we cannot use the prediction accuracy of different models to compute model weights. Consequently, all models receive the same weight (e.g., in IPCC reports or for economic models), or some reasonable but statistically ad-hoc construction of weights is employed (e.g., Giorgi and Mearns 2002). In recent years, hind-casting has gained in popularity, i.e., evaluating models by predicting to past data. This will only be a useful approach if historic data were not already used to derive or tune model parameters, and if hindcasting success is related to prediction success (which it need not be, if processes or drivers change).

Cross-validation is often infeasible for large models, as run-times are prohibitively long. However, the greatest obstacle to averaging process models is the absence of truly equivalent alternative models, which predict the same state variable. Fishery science is one of the few areas of ecology in which commensurable models exist and are being averaged in a variety of ways (e.g., Stanley and Burnham 1998, Brodziak and Legault 2005, Brandon and Wade 2006, Katsanevakis 2006, Hill et al. 2007, Katsanevakis and Maravelias 2008, Hollowed et al. 2009, Jiao et al. 2009, Brodziak and Piner 2010). Carbon and biomass assessments are also moving in that direction (Hanson et al. 2004, Butler et al. 2009, Wang et al. 2009, Picard et al. 2012). These fields could profit from exploring averaging methods such as minimal variance and cos-squared, which do not require cross-validation and may perform better than either equal weights or BMA-EM, and probably better than MBMC’s potentially overfitted supra-models.

Finally, irrespective of the approach chosen, model averaging studies should report model weights, and predictions should be accompanied by estimates of prediction uncertainty.

**Overall conclusion and recommendations**

In conclusion, we find that:

1) Model averaging may, but need not necessarily reduce prediction errors. Model averaging benefits generally increase with decreasing covariance of the individual model predictions and decreasing mean bias of the contributing models. Moreover, while estimating model weights allows reducing the weight of poor models, this comes at the expense of introducing additional variance in the average, reducing the benefits of model averaging.

2) There are currently no generally reliable analytical methods to calculate frequentist confidence intervals (or P-values) on model-averaged predictions. Non-parametric methods, however, such as cross-validation, remain reliable for estimating predictive errors, and should therefore be preferred for quantifying predictive uncertainties of model averages. Bayesian credible intervals are in principle valid as well, if the typical assumption for Bayesian model selection, that the true model is among the candidates, is met.

3) From general considerations, we believe that non-parametric methods that directly target predictive error (e.g., cross-validation or stacking) are a robust and straightforward choice for choosing weights. Parametric methods such as AIC, BIC are faster, but may not always perform equally well. Cross-validation can be used to test if fixed or estimated weights perform better than the full or the best model.

**Acknowledgments**

We are grateful to five meticulous reviewers and the editor for providing substantial and constructive feedback, which greatly improved the previous versions of this manuscript. We would like to thank the German Science Foundation (DFG) for funding the workshop “Model averaging in Ecology,” held in Freiburg 2-6 March 2015 (DO 786/9-1). Part of this work was carried out during a research stay of C. F. Dormann at the University of Melbourne, co-funded by the DFG (DO 786/10-1). B. Schröder is supported by the DFG (SCHR1000/6-2 and SCHR1000/8-2). D. J. Warton is supported by an Australian Research Council (ARC) Future Fellowship (grant number FT120100501). D. R.
