Short title: \textit{Decision to move}
Abstract (196 words)

All animals use sensory systems to monitor external events and have to decide whether to move. Response times are long and variable compared to reflexes, and fast escape movements. The complexity of adult vertebrate brains makes it difficult to trace the neuronal circuits underlying basic decisions to move. To simplify the problem, we investigate the nervous system and responses of hatchling frog tadpoles which swim when their skin is stimulated. Studying the neuron-by-neuron pathway from sensory to hindbrain neurons where the decision to swim is made has revealed two simple pathways generating excitation which sums to threshold in these neurons to initiate swimming. The direct pathway leads to short, and reliable delays like an escape response. The other includes a population of sensory processing neurons which extend firing to introduce noise and delay into responses. These neurons provide a brief, sensory memory of the stimulus, that allows tadpoles to integrate stimuli occurring within a second or so of each other. We relate these findings to other studies and conclude that sensory memory makes a fundamental contribution to simple decisions and is present in the brainstem of a basic vertebrate at a surprisingly early stage in development.

1. Introduction

In 100m sprint races, men take 120 to 165ms to start moving [1]. Such response times fascinated experimental psychologists since Helmholtz (1850) described methods to measure them [2]. Coordinated movements, like eye movements towards a new target, start after variable delays of 50 to 200ms [3]. Why are these responses slow and variable when reflex movements and the rapid escape responses of animals like squid, crayfish and fish, have short and constant response times (RTs; < 20ms) [4-6].
Studies of response times have focussed on eye movements of people and other mammals, especially monkeys and on the complex neuronal circuits in the prefrontal motor cerebral cortex which control them [7-9]. In the simplest experiments, subjects gaze at a light spot and are required to shift their gaze to another light spot when it comes on. Recordings of neuronal activity in mammals have shown that sensory information travels from the eyes to the cerebral cortex where it influences the ongoing firing of neurons. When the light flashes briefly, a “sensory memory” of the stimulus is needed and this too has been studied primarily in cerebral cortex. The memory only lasts for a second or so, and is proposed to be based on mutual re-excitation within small populations of neurons [10-12]. During the lead-up to the decision to move the eyes, recordings in primate and rat pre-frontal cortex have shown that the stimulus results in a slow and noisy build-up of firing frequency. In some neurons, peak firing rates correlate with the decision to move.

Many theories underlying decisions to move the eyes propose that an excitatory “decision signal” builds noisily to a threshold in cortical neurons and, when this is reached, the movement occurs (Fig. 1a) [3, 13-15]. Variability in response times results from noise in the decision. The complexity of cortex makes the neuron-by-neuron circuits and synaptic properties of decision making impossible to define. Furthermore, the advantages of slowing down decisions to move are unclear. Do they allow other stimuli and central states to be taken into account before a response is made?

Analysis of simpler neuronal circuits should help to understand the details of how neuronal circuits control the initiation of coordinated motor responses to a sensory stimulus. It is disheartening that the only cases where the neuron-by-neuron pathway from a sensory stimulus to a response have been traced are those for the rapid escape
movements controlled by giant neurons in crayfish [5, 16] and in fish [17]. This is a consequence of the ease of study of giant neurons and the difficulties imposed by the small size of most neurons.

2. Why use tadpoles to study the initiation of movements?

Larval fish and amphibians provide useful models for studying the foundations of vertebrate nervous development, organisation and function [18, 19]. We have investigated the neurons, and networks that allow hatchling *Xenopus laevis* tadpoles (Fig. 1b) to behave and survive [20-22]. This has led to some surprising new discoveries about the organisation of sensory systems, sensory memory and the neurons where the decisions to move are made [23-25].

As in adult animals, tadpole response times for swimming following skin stimulation are long and variable. If touched on one side of the trunk with a fine hair, tadpoles flex unpredictably to left or right and then swim off [26]. The response times to swimming following a brief current pulse (Fig. 1c) are long and variable (median 102 ms, Inter Quartile Range 81-136 ms; Fig. 1d; [25]).

Tadpoles also have to decide which side will flex first. We have studied this by immobilising tadpoles so that recordings can be made from motor nerves and one or two individual neurons in the spinal cord and brain. When a near threshold current pulse is given to the skin on one side of the head, the first motor nerve burst has a ~0.5 probability of being on the stimulated or unstimulated side (Fig. 1e; [24]). Reaction times are shorter than behavioural responses but are still long and variable (stimulated side starts: median 25ms, range 15 – 87; unstimulated side starts: median 35ms, range 20 –
71) compared to reflexes (<10 ms; [27]). When the trunk skin is stimulated, the median delay to the first motor nerve firing on the unstimulated side was 40ms (IQR 33–61; [25]). In this review, we discuss where and how the delays and their variabilities arise in the tadpole’s decision to swim.

3. Overview of the tadpole skin sensory swimming initiation pathway

To find out about the different types of neuron, their anatomy, activity, and synaptic connections, we have used dye filled electrodes to record from pairs of neurons in the brain and spinal cord of immobilised tadpoles. This has allowed us to build a broad picture of how the neuronal networks they form are organised [20, 21]. The tadpole skin touch to motor pathway has five functional stages (Fig. 2), as does the leech [28].

(1) Touch sensory neurons for the head skin lie in the trigeminal ganglia and for the trunk skin in the spinal cord [29, 30]. A single AP (action potential) in one or two sensory neurons can initiate swimming. Their peripheral axons carry APs into the CNS where their central axons project to distribute excitation longitudinally.

(2) Sensory pathway neurons are excited by sensory neurons and distribute sensory signals to both sides of the brain [23, 30]. Single sensory neurons excite many sensory pathway neurons and in this way the sensory signal is amplified [27]. Trigeminal sensory pathway neurons are only excited by head skin stimuli and make direct connections to level 4 reticulospinal neurons [23].

(3) Sensory processing neurons are a new and important proposal for the movement initiation pathway [25]. The preliminary evidence and definition of these neurons suggests that they extend firing (possibly by mutual re-excitation) and introduce noise and variability. They transform the short or nearly synchronous firing in sensory pathway
neurons (<30 ms) into longer lasting and variable firing (~ 1000 ms) which is different in each neuron of their population. They are excited by sensory pathway neurons and excite reticulospinal neurons. Their firing acts as a sensory memory of any brief sensory stimulus to the skin.

(4) Reticulospinal neurons lie in the hindbrain and project to the spinal cord. They sum the input from different sensory pathways and modalities, like skin touch and light [31]. It is here that excitation from sensory processing neurons builds up noisily and can reach firing threshold. It is these reticulospinal neurons that effectively make the decision to swim because, when they fire, motoneurons are activated and initiate the first flexion of swimming. During swimming they generate the rhythm by firing once on each cycle.

(5) Motoneurons and reciprocal inhibitory neurons are excited strongly by the reticulospinal neurons so they fire once on each cycle of swimming [32]. Motoneuron firing leads to muscle contraction and flexion of the body. Alternation of firing is organised by reciprocal inhibition [33], re-enforced by post-inhibitory rebound firing organised by the same reciprocal inhibition [21, 34]. The result is alternating waves of contraction and swimming.

4. Evidence on the operation of the tadpole touch sensory system

Sensory neurons innervate the skin in all vertebrates with fine unspecialised “free” nerve endings which wrap around the skin cells. Tadpole sensory neurons (tSt) for head skin lie in the trigeminal ganglia and their central axons reach the brain in the 5th cranial nerve [29]. The trunk skin has similar endings coming from sensory Rohon-Beard (RB) neurons in the spinal cord [30, 35]. Recordings from sensory neurons showed that they fire 1 to 3 spikes when stimulated in their receptive field.
Spinal sensory pathway neurons are excited by synapses from the longitudinal axons of skin sensory neurons. In the spinal cord, recordings from pairs of neurons, show that the RB neurons directly and strongly excite two types of sensory pathway neuron (Fig. 3a; [27, 36, 37]). These dorsolateral commissural (dlc) and ascending (dla) neurons only fire very briefly.

Trigeminal sensory pathway neurons (tINs) form a small trigeminal nucleus of around 25 neurons on each side of the hindbrain and have descending axon [23]. Head skin sensory neurons directly excite tINs and more rostral spinal sensory pathway neurons (rdlcs; [24]).

Sensory pathway neurons: distribute signals from skin sensory neurons to targets on both sides of the brain; amplify sensory signals so one or two spikes in a few sensory neurons elicit a single spike in many pathway neurons (the number firing may depend on the number of sensory neurons firing and crudely code the stimulus strength); set a limit on the excitation reaching the brain because there is a fixed number of them.

5. Evidence on the activation of the swimming control system

Movements of the body and limbs in vertebrates are thought to be controlled by reticulospinal neurons in the hindbrain which project to the spinal cord [38-42]. Tadpole swimming starts when a population of hindbrain reticulospinal neurons (hdINs) becomes active [20, 23, 24, 32]. These neurons are electrically coupled [43], so when a few fire, the whole population on one side is recruited and they all fire once in synchrony [44]. They then play a critical role in driving swimming [21, 45]. As well as exciting motorneurons and other spinal neurons, these electrically coupled neurons excite each
other chemically by releasing glutamate [32]. Mutual activation of their own NMDA receptors turns on pacemaker properties which sustains their own regular, rhythmic firing and swimming [44, 46-48].

It was therefore surprising when recordings from these reticulospinal hdINs showed that the only sensory pathway neurons to make strong and direct synaptic connection to them were the hindbrain (tINs) excited by head skin stimulation (Fig. 3b). This pathway could evoke hdIN firing and swimming starting on the stimulated side at relatively short latencies (hdINs: median delay of 12 ms; motor nerve: median 25 ms; [24]. To our knowledge, this is the first simple, non-giant neuron pathway for the initiation of locomotion defined in the vertebrates.

How does a stimulus to one side lead to swimming starting on the opposite side?

Spinal sensory pathway dlc neurons carry excitation to the opposite side when the head or trunk skin is stimulated. Surprisingly, recordings from these neurons and hdINs on the opposite side showed no direct, short latency excitation (Fig. 3c; [24]) but revealed a very variable pattern of longer latency excitation [25]. This could build up over time to reach the hdIN threshold so they fired at long and variable latencies (Fig. 3c, d; median 57 ms). The response times of the first hdIN firing matched the delays to the start of swimming in motor nerve recordings (Fig. 1e).

What are the characteristics of the variable pattern of excitation recorded in reticulospinal dINs following a brief skin stimulus? Even when the stimulus was too weak to evoke swimming, hdINs on each side of the body received long-lasting excitation with clear EPSPs occurring for many hundreds of ms after the stimulus (Fig. 3e - f) [25]. It is difficult to see how this pattern of EPSPs could be produced directly by
the brief burst of spikes fired early by sensory pathway dlc neurons. The EPSPs must be generated by unidentified neurons firing irregularly for some time after skin stimulation. We obtained information about the timing of the APs in these unidentified neurons by measuring the timing of the EPSPs they evoked in hdINs following skin stimulation (Fig. 3e). The novel conclusion was that the sensory pathway neurons must excite undefined populations of sensory processing neurons on each side of the brain whose function was to extend sensory firing for about 1 second, act as a sensory memory of brief stimuli, and produce variable excitation of the hdINs to initiate swimming. We call them extension neurons (exNs) and have candidate recordings of hindbrain neurons with suitable prolonged and variable firing to skin stimulation (Fig. 3g).

6. A model of sensory memory to extend brief sensory firing

How could sensory pathway neuron firing and excitation be extended by sensory processing exN neurons in the hindbrain? A simple proposal is that exN neurons excite each other to form a small recurrent network and sustain their own activity for a short time [10]. To test this idea, we built a network of 30 model exN neurons excited by brief excitation from sensory pathway dlc neurons. The exNs were connected to a model hdIN [48] to monitor the synaptic excitation they produced. With variability in the synaptic strength of all excitatory synapses in the network (maximum conductance of each synapse scaled by a randomly chosen value: 0.8, 0.6, 0.4, 0.2 or 0), the variable patterns of exN firing it generated could be qualitatively matched to the data on the timing of EPSPs in hdINs. These results show that it is simple to prolong firing in a small model network of unspecialised neurons if there is variable and weak recurrent excitation among them even without any inhibition [25]. If such a network was connected to hdINs in a model swimming network it should start swimming after variable and
unpredictable delays.

7. Discussion

All animals have to make decisions about whether to respond to sensory stimuli. Studying simpler animals, can uncover the detailed neuronal pathways for decisions to initiate simple movements, like swimming [28]. In crayfish and fish escape responses, sensory neurons directly excite giant neurons, bringing them rapidly to firing threshold. They fire a single spike, and the first flexion of swimming is initiated at a short and constant latency by the direct excitation of motorneurons [16, 17].

In hatchling tadpoles, tracing the neuronal pathway from a brief skin touch to the initiation of swimming, has revealed two ways in which populations of non-giant reticulospinal neurons (hdINs) can control the first flexion of swimming (Fig. 2). Stronger head skin stimulation excites tIN neurons on the same side of the hindbrain [23] and they directly excite the hdIN population and swimming follows at fairly short and constant latencies [24]. This pathway provides a simple and direct way to initiate locomotion. Weaker stimuli to the head or trunk have revealed unexpected complexity. Instead of a simple reflex-like pathway, we propose that small populations of sensory processing neurons (exNs) in the hindbrain are excited by sensory pathway neurons and extend firing for approximately 1 second (see Fig. 2 level 3; [25]. This process could introduce noise into the sensory signal in the brain and then provide prolonged, excitation to the reticulospinal hdINs to bring them to firing threshold, so swimming is initiated after variable delays on either side of the body. The exNs therefore combine two functions: they hold a roughly 1 second sensory memory of recent stimuli and generate a noisy
“decision signal” to brainstem hdlNs. The hdlN firing is the “decision” which initiates the first flexion of swimming after variable delays.

What is the significance of extending sensory excitation and inserting delay and noise into the movement initiation pathway?

(i) **Integration of sensory inputs** is made possible by the long-lasting excitation exNs produce in reticulospinal hdlNs. If an initial stimulus does not lead to a motor response, then this excitation remains present and could sum with excitation from subsequent stimuli to the same location (temporal summation) or to other parts of the body (spatial summation). In addition, other sensory modalities like water currents [49] and light dimming [31] can initiate swimming. Extended excitation in hdlNs acts as a sensory memory and could sum with other sensory inputs if they occur within the 1 second time window. Neurons with extended excitation can therefore act as integrators, so responses are “considered” in the context of all stimuli reaching the animal.

(ii) **Motor coordination** is essential for the production of effective movements. When stimulated, the tadpole must decide whether or not to make the first body flexion of swimming, and which side flexes first. This is a very organised process in response to head skin stimulation [24]. The hdlN firing on each side falls into discreet alternating time windows, so synchronous firing of the two sides is avoided. It is very likely that reciprocal inhibition is important here [33, 50]. However, in *Xenopus* immobilised preparations synchronous firing of both sides can occur [51, 52] as in simple model networks with reciprocal inhibition [34, 53]. Slowing down hdlN excitation and making it noisy, probably reduces the chance of hdlNs reaching firing threshold simultaneously on both sides, thus reducing the probability of synchronous firing.
(iii) **Introducing variability** into responses may make responses less predictable and help animals to avoid predation [54]. The slowly rising excitation in hdlNs following skin stimulation introduces variability into: the delay before hdlNs reach their firing threshold and swimming starts; the side which fires first to gentle stimulation; and the direction of swimming. There is one exception to this general picture. Stronger stimuli to the head skin lead to short latency and predictable flexion towards the stimulated side [24] and the biological significance of this behaviour is not clear.

8. **Overview of a simple decision to move**

Can the complete neuron-to-neuron pathway from a sensory stimulus to a **coordinated motor response** be defined? At present the only examples are those specialised for fast responses [16, 17, 23]. The latencies to most skin stimuli in tadpoles are long and variable, like eye movements and other coordinated motor responses in adult animals [3]. Our new evidence on tadpole swimming initiation is still incomplete but has a surprising new sensory processing stage (Fig. 2). We propose that neurons at this stage extend and add noise to the signal reaching the brainstem reticulospinal neurons which drive swimming. The evidence supports the basic proposals from studies on eye movements where variable excitation leads to long and variable response times. The evidence that some hindbrain neurons produce variable excitation is strong but characterisation of the neurons involved is at present weak. Our expectation is that neurons performing this extension or sensory memory function will be a fundamental component of movement initiation pathways in most animals. The slowing down of responses allows animals to integrate multiple sensory inputs and to make “considered” rather than “rash” responses!
