This work presents the design, fabrication and measurement of gallium nitride (GaN) distributed Bragg reflector cavities integrated with input and output grating couplers. The devices are fabricated using a new, low-cost nanolithography technique: displacement Talbot lithography combined with direct laser writing lithography. The finite-difference time-domain method has been used to design all the components and measured and modelled results show good agreement. Such devices have applications in GaN integrated photonics and biosensing.

1. Introduction: Gallium nitride (GaN) is a promising candidate for many integrated photonics applications [1–6]. It is transparent from ~400 nm to ~13.6 μm [7], has a relatively high refractive index of ~2.4 and is used as the basis for a range of visible LEDs and lasers [8–12], including vertical cavity surface emitting lasers [13]. These unique properties have been used in photonic integrated circuits and led to recent work developing GaN as a chemical and biological sensing platform [14]. GaN-based waveguides have achieved low loss [15,16] and have been implemented as freestanding waveguide structures [17–19]. GaN-based photonic crystal cavities have also been developed and high Q factors have been obtained which can be used to sense biological or chemical analytes [20,21]. Although the technology of GaN waveguides is not as mature as silicon-on-insulator [22], the characteristics of GaN discussed above act as an impetus to further explore photonic integrated circuits in this technology. The fabrication of GaN waveguides and photonic crystal cavities is almost always based on electron beam lithography. Although the accuracy of this method is very high, the manufacturing process is slow and is very expensive. This work aims to design a waveguide integrated GaN distributed Bragg reflector (DBR) cavity using a new nanolithography technique: displacement Talbot lithography (DTL), which can produce large area, nanoscale periodic structures with low-cost and high-throughput [23,24]. Basic results were shown in [25], here we show in-depth modelled and measured results along with fabrication details and waveguide loss measurements.

The proposed structure is shown in Fig. 1, which includes two GaN gratings couplers and two GaN DBR gratings forming a cavity. The use of DTL fabrication restricts the period of all gratings to be nominally the same across the whole wafer, with laser lithography being used to define the region where the gratings are present. In future structures it may be possible to have different etch depths for different gratings, but for different gratings, but here we have restricted processing to a single etch step. These limitations are not ideal for forming both grating couplers and DBR cavities, but compared to the very high cost of electron-beam lithography, DTL + DLW (direct laser writing) is an interesting much lower cost option and this Letter shows the potential for this approach.

2. Grating couplers
2.1. Modelling and design: We used the two-dimensional finite-difference time-domain (FDTD) technique from Numerical FDTD Solutions [26] to optimise the maximum output coupled power for a 1.5 μm layer of GaN-on-Sapphire. Fig. 2 shows the 2D schematic cross-section for the in–out grating coupler structure.

In the model, a fundamental transverse electric (TE0) mode source comes from a fibre which is single mode around the wavelength of interest which is 630–640 nm. This was initially based on the fact that a red laser would be used to show simple light coupling, this was eventually replaced with a supercontinuum laser source. Thus, the fibre is a SMF600 with 125 μm cladding diameter and 4.3 μm core diameter. Light from the fibre will be diffracted into the reflected and transmitted orders. Some of the transmitted orders which satisfy the guided mode conditions can propagate in the 120 μm long waveguide and be coupled out into free space, then collected by an identical single-mode fibre at the output. The simulation uses a wavelength range of 450–900 nm and is mainly focused on optimising across the 630–640 nm wavelength range. The gratings and waveguide are in the GaN layer with a refractive index of gallium nitride (GaN) discussed above act as an impetus to further explore photonic integrated circuits in this technology. The fabrication of GaN waveguides and photonic crystal cavities is almost always based on electron beam lithography. Although the accuracy of this method is very high, the manufacturing process is slow and is very expensive. This work aims to design a waveguide integrated GaN distributed Bragg reflector (DBR) cavity using a new nanolithography technique: displacement Talbot lithography (DTL), which can produce large area, nanoscale periodic structures with low-cost and high-throughput [23,24]. Basic results were shown in [25], here we show in-depth modelled and measured results along with fabrication details and waveguide loss measurements.

The proposed structure is shown in Fig. 1, which includes two GaN gratings couplers and two GaN DBR gratings forming a cavity. The use of DTL fabrication restricts the period of all gratings to be nominally the same across the whole wafer, with laser lithography being used to define the region where the gratings are present. In future structures it may be possible to have different etch depths for different gratings, but for different gratings, but here we have restricted processing to a single etch step. These limitations are not ideal for forming both grating couplers and DBR cavities, but compared to the very high cost of electron-beam lithography, DTL + DLW (direct laser writing) is an interesting much lower cost option and this Letter shows the potential for this approach.

2. Grating couplers
2.1. Modelling and design: We used the two-dimensional finite-difference time-domain (FDTD) technique from Numerical FDTD Solutions [26] to optimise the maximum output coupled power for a 1.5 μm layer of GaN-on-Sapphire. Fig. 2 shows the 2D schematic cross-section for the in–out grating coupler structure.

In the model, a fundamental transverse electric (TE0) mode source comes from a fibre which is single mode around the wavelength of interest which is 630–640 nm. This was initially based on the fact that a red laser would be used to show simple light coupling, this was eventually replaced with a supercontinuum laser source. Thus, the fibre is a SMF600 with 125 μm cladding diameter and 4.3 μm core diameter. Light from the fibre will be diffracted into the reflected and transmitted orders. Some of the transmitted orders which satisfy the guided mode conditions can propagate in the 120 μm long waveguide and be coupled out into free space, then collected by an identical single-mode fibre at the output. The simulation uses a wavelength range of 450–900 nm and is mainly focused on optimising across the 630–640 nm wavelength range. The gratings and waveguide are in the GaN layer with a refractive index of GaN [28]. The substrate is sapphire with a refractive index of sapphire [28], and the cover region is air.

There are four main design parameters for the grating couplers: grating period, filling factor, etch depth and number of periods, where grating period λ = L + L, and filling factor a = L/A. In addition, the fibre angle of incidence plays an important role. In our case this was fixed at 15° based on the available optical measurement set up. The main design choice to be made is the grating period and diffraction theory can be used to determine the optimum value and this is simplest when the waveguide is single mode [29]. However, in our case the GaN slab waveguide is highly multimode, supporting 8 TE modes around 630–640 nm wavelength. Thus in our case, we based our choice on available DTL masks and decided on a 400 nm period grating. FDTD modelling was then used to determine the impact of etch depth and filling factor in order to guide the fabrication process. The number of periods was chosen as 45 giving a grating length of 18 μm which was felt to be sufficiently large with respect to the fibre core diameter of 4.3 μm. A waveguide length of 120 μm was chosen as a balance between simulation memory requirements and obtaining realistic results for waveguides that would be much longer in practice. In the FDTD modelling, by varying the etch depth ranging from 0 to 1500 nm and fill factor from 0.2 to 0.8, it was found that the TE0 mode input source has an optimum in–out transmittance at 640 nm wavelength when the fill factor is...
2.2. Fabrication: Since the process was to employ only a single GaN etch step using a 450 nm-thick plasma-enhanced chemical vapour deposition SiN, hard etch mask, multiple lithography steps were required to pattern the SiN mask beforehand. This is due to the different capabilities of the two lithography techniques: DTL can pattern periodic nanoscale features but only with large areas, whereas DLW can pattern arbitrary features >1 µm. Three different regions on the mask are required: large areas of SiN, to protect the waveguide, grating patterns for the couplers and the DBRs, and large unprotected areas in order to surround the waveguide.

The first step of the fabrication process was to define the large waveguide features in the mask. A S1813 positive photoresist mask was patterned via DLW (µPG 101, Heidelberg Instruments) and then transferred into the SiN via ICP etching using CHF₃ chemistry. This resist was then removed before applying a second, 350 nm-thick, high-resolution, AZ1518 negative photoresist layer (on top of a Wide 8C bottom anti-reflective coating to improve resolution). This was exposed via DTL (PhableR 100C, EULITHA) to create a 400 nm-pitch grating in the resist across the whole sample area. A second exposure via DLW then fully exposed the negative resist in all areas where gratings were not required before CHF₃ plasma was used to transfer the resist pattern into the SiN. In this way, small grating regions could be created in the SiN, whilst the negative resist protected the surrounding sample. The resist was subsequently removed.

The resulting SiN was used as a mask to etch ~780 nm of GaN using Cl₂/Ar plasma. A high etch temperature of 150°C was used to ensure vertical sidewall etch profiles [30]. Finally, the SiN mask was stripped in HF-based solution.

the unpolarised light to the input fibre. To avoid the possibility that
direct coupling damages the fibre facet, two achromatic objectives
are added to couple from laser into free-space, then into the fibre.
An Ocean Optics spectrometer is used to collect in–out coupling
intensity data. A high-magnification camera is used to show a
plan-view and the location of fibres on the sample. The second
camera shows a side-view to check the vertical distance between
the fibre facets and sample.

The layout of part of the chip is shown in Fig. 8. A series of
100 μm × 100 μm area grating couplers with varying waveguide
lengths are located in this area.

The plan-view image of GaN grating couplers and waveguide is
shown in Fig. 9a. The output grating can be seen to be bright in
Fig. 9b when the output fibre is removed, showing that reasonable
coupling has been obtained.

The in–out coupling measurement results with varying wave-
guide length are shown in Fig. 10a. It can be seen that there are
two regions of high transmittance around 640 and 700 nm and
this matches up well with the TE0 + TM0 mode result shown in
Fig. 6. There is some variation in the peak wavelength between
the 6 waveguide lengths, but this is expected due to the fabrication
differences between gratings in the different waveguides. In the
case of the 1 mm waveguide there is a strong ripple with a peak
spacing of 4.1 nm. It is believed that this ripple is related to mode
beating [31] between the multiple modes that can propagate in
the waveguide and the mode spacing is of the order that would
be expected for this length of waveguide. The longer waveguides
do not have such a prominent ripple, but these will have higher
loss, and this will tend to suppress the mode beating effect.

The coupling loss and waveguide attenuation are estimated by
the cutback method. In order to accurately calculate the coupling
loss, the input fibre should be connected directly to the output
to act as a reference, however in our current set up this was not
possible. Thus, in order to make an approximate estimate for
coupling loss, a silver mirror placed in the position of the chip
was used as a reference. This will significantly underestimate the
coupling loss and in future work we will improve this coupling
loss estimate. Fig. 10b shows the transmittance at 639 nm normal-
ised to the mirror transmittance for each waveguide length. In the
case of the 1 mm length, due to the strong ripple an estimate was

required which removed the effect of these ripples. The slope of the linear fit gives the waveguide loss to be 3.9 dB/mm. The coupling loss, compared to the mirror transmittance, is obtained as the intercept with the vertical axis and is found to be 2 dB in total or 1 dB per coupler.

3. DBR cavity

3.1. Modelling and design: Next, we focus on the DBR cavity design. The schematic representation of an isolated cavity is shown in Fig. 11. It consists of two 400 nm period DBR gratings forming a cavity. As described above, we represent unpolarised light with a TE0 + TM0 mode source. The length of the cavity was chosen to be 8 μm, ensuring that there is sufficient length to observe resonant peaks, and the filling factor and etch depth remain unchanged at 0.5 and 780 nm, respectively.

The modal transmittance of Fig. 12 is for 25 period DBR gratings with an 8 μm cavity. A mode spacing of ~10 nm can be seen at an etch depth of 780 nm around 640 nm wavelength which will allow approximately two resonant peaks to be observed in the bandwidth of the grating coupler, shown in Fig. 10a. It can be seen that 780 nm etch depth is an optimum for resonant cavity behaviour. In order to understand these effects further, we can use FDTD to look at the fields at one of the resonant peaks, shown in Fig. 13.

![Image](image_url)

**Fig. 13** \( E_z \) field distribution in cross-section for the peak wavelength (637 nm), TE0 + TM0 modes propagating from left to right. Grating parameters: filling factor = 0.5, period = 400 nm, cavity length = 8 μm (vertical and horizontal axes not to scale)

a Etch depth = 500 nm
b Etch depth = 780 nm
c Etch depth = 1100 nm
d Etch depth = 1500 nm
Fig. 13 shows the magnitudes of the $E_z$ field for TE$_0$ + TM$_0$ modes with different etch depths at wavelength of 637 nm which is one of the resonance peaks. At 500 nm etch depth, because the structure is not fully etched, most of the light propagates in the region beneath the Bragg grating and does not couple into the cavity, so as shown in Fig. 12, no obvious resonance peaks are observed. As the etching becomes deeper, more light couples into the cavity and at a depth of 780 nm a significant amount of light is coupled into the cavity and this results in the resonances observed in Fig. 12. As the etch becomes deeper, the amount of light propagating through the first DBR decreases significantly and this reduces the resonant behaviour and in the case of full etching, removes any resonances completely. It can be seen that since the waveguide is multimode, very non-ideal operation is observed for this structure. In future work, thinner GaN layers and ridge waveguide structures will be used to ensure single mode operation which will simplify device operation significantly.

Fig. 14 shows the layout for one DBR cavity on the chip and Fig. 15 shows an SEM picture of a typical 10 μm long cavity. There are some unetched portions of the DBRs which will cause some differences between measured and modelled results.

3.2. Measurement: The zoomed in-out coupling with DBR cavity measurement results is shown in Fig. 16 for two different devices on the same chip and it can be seen that similar performance is obtained. However, a mode spacing of 10 nm is observed in one case, but not for the second device. Since the waveguide is highly multimode, the mode spacing will depend on which modes are resonating in the cavity and the defects shown in Fig. 15 will also produce non-ideal results. Insets show visible light camera images of both cavities which shows significant scattering from the first DBR and evidence of the high-intensity peaks within the cavity.

4. Conclusion: This Letter has shown GaN DBR cavities with grating couplers fabricated using DTL. Cavities with $Q$ factors of >200 have been measured which show the potential for this route to low-cost commercial sensor applications. In future work, single-mode waveguides will be fabricated which will result in much more idealised grating coupler and cavity behaviour which will lead to increased device performance. The main restriction for the DTL approach is that all gratings must have the same period, but with correct processing, different etch depths and fill factors could be obtained which would further improve the device performance.
