Abstract

Much of the recent masked nonword priming literature demonstrates no difference in priming between affixed and non-affixed nonword primes (e.g., *maskity-MASK* vs *maskond-MASK*). A possible explanation for the absence of a difference is that studies have used affixed primes which were semantically uninterpretable (Heathcote, Nation, Castles, & Beyersmann, 2017). Therefore, this explanation indicates semantic interpretability plays a fundamental role in masked priming. To test this account, we conducted an experiment using the masked priming paradigm in the lexical decision task. We compared responses to targets which were preceded by one of four primes types: 1) interpretable affixed nonwords (e.g. *maskless-MASK*), 2) uninterpretable affixed nonwords (e.g. *maskity-MASK*), 3) non-affixed nonwords (e.g., *maskond-MASK*) and 4) unrelated words (e.g. *tubeful-MASK*). Our results follow the trend of finding no difference between affixed and non-affixed primes. Critically, however, we observed no difference in priming between uninterpretable and interpretable affixed primes. Thus, our results suggest that semantic interpretability does not influence masked priming.

Keywords: semantic interpretability, masked priming, morphological processing, visual word recognition, lexical decision

Semantic interpretability does not influence masked priming effects

The role of morphological processing in the visual identification of complex words has been the subject of intensive study by psycholinguists. Morphemes are the building blocks of language, and the ability to recognise, analyse and combine morphemes is critical for comprehension and production in skilled language use. For example, in order to understand a new word like *unfriend* we need to be able to identify its component morphemes. Evidence suggests that this process of decomposing a word into its morphemes continues to be important even after the word has become familiar in its whole word form (see Rastle & Davis, 2008 for a review). Thus, research over the last couple of decades has focussed on questions relating to how and when decomposition occurs. What information do readers make use of to decompose a complex word into its morphemic constituents, and does this occur before or after the lexical representation of the word is accessed?

Masked priming with word primes

A popular technique for investigating these issues is masked priming (e.g., Crepaldi, Hemsworth, Davis, & Rastle, 2016; K. I. Forster, Davis, Schoknecht, & Carter, 1987; Frost, Forster, & Deutsch, 1997; Grainger, Colé, & Segui, 1991; W. Marslen-Wilson, Tyler, Waksler, & Older, 1994; Rastle, Davis, Marslen-Wilson, & Tyler, 2000). For example, participants can respond (e.g., by making a lexical decision) more rapidly to a target word like *READ* when it is preceded by a brief (~50 ms) presentation of a related morphologically complex word like *reader* than when it is preceded by a unrelated control word. Critically, this priming effect is greater than would be expected on the basis of semantic or orthographic information (e.g., Drews & Zwitserlood, 1995; Rastle et al., 2000). For example, Rastle et al. (2000) found that priming was

1
2
3 greater for morphologically related prime-target pairs like *vagueness-VAGUE* than for prime-
4 target pairs like *electrode-ELECT*, where there is equal orthographic overlap but no
5 morphological relationship. Such priming effects have been interpreted as evidence of an early
6 morphological relationship. Such priming effects have been interpreted as evidence of an early
7 process that rapidly decomposes a prime into its morphemes, facilitating identification of the
8 morpheme shared by prime and target.
9

10
11
12
13
14
15 Further evidence concerning the nature of this early decomposition process was provided
16 by experiments reported by Longtin, Segui, and Hallé (2003) and Rastle, Davis, and New (2004),
17 who investigated the effect of pseudoaffixed word primes like *corner*, which have the
18 orthographic appearance of affixed forms, but have no genuine morphological or semantic
19 relationship to the target (i.e., a *corner* is not one who corns). These researchers found that
20 masked priming effects for *corner-CORN* were just as great as for transparently related pairs like
21 *darkness-DARK*, and significantly greater than for orthographic control primes like *brothel-*
22 *BROTH* (where *-el* is not an English affix). Rastle and Davis (2008) concluded that this early
23 decomposition process is based entirely on orthography and is blind to semantics. In addition to
24 these initial investigations in French and English, similar results have been reported in Dutch
25 (Diependaele, Sandra, & Grainger, 2005), Hebrew (Frost et al., 1997), Spanish and Basque
26 (Duñabeitia, Perea, & Carreiras, 2007) and Russian (Heyer & Kornishova, 2018; Kazanina,
27 2011).

44
45

46 Although some studies have reported significantly greater priming for transparent than for
47 opaque primes (e.g., Diependaele et al., 2005; Feldman et al., 2015), these empirical differences
48 can probably be attributed to methodological differences (see Davis & Rastle, 2010). In
49 particular, the difference between transparent and opaque primes is modulated by prime duration:
50
51
52
53
54
55
56
57
58
59
60
When there is sufficient time for semantic processing to occur, priming is not observed for

1
2
3 opaque forms. There is still some uncertainty concerning what constitutes sufficient time, but a
4 reasonable estimate is 60 ms (in the masked priming paradigm, primes that are presented for
5 longer than this duration are often consciously perceived, though of course this need not imply
6 that conscious awareness is a critical factor). Indeed, Heyer and Kornishova (2018) investigated
7 whether the difference in priming effect size between opaque and transparent primes would
8 emerge regardless of prime duration. A significant difference between opaque and transparent
9 primes appeared for trials involving a long prime duration (77 ms). However, this difference did
10 not occur for trials involving a short prime duration (39 ms). Currently, the general consensus in
11 the literature is that a difference between transparent and opaque primes is likely to be observed
12 for primes that are presented for durations longer than 60 ms (e.g., Diependaele et al. (2005);
13 Rastle et al. (2000); Feldman et al. (2015)), whereas a difference is unlikely to be reported for
14 primes that are presented for durations less than 50 ms (see Davis & Rastle, 2010 for a meta-
15 analysis).

30
31
32
33
34 There are a minority of studies which demonstrate semantic transparency effects with
35 prime durations of 50ms (e.g. Morris, Frank, Grainger, & Holcomb, 2007). However, this
36 discrepancy in findings could again be attributed to methodological differences (Davis & Rastle,
37 2010). For example, while most studies which have reported no difference in priming between
38 opaque and transparent primes used forward masking (e.g. Gold and Rastle, 2007; Kazanina,
39 Dukova-Zheleva, Geber, Kharlamov, & Tonciulescu, 2008), studies like Morris et al (2007) used
40 backward masking. In summary, a large body of evidence has been amassed to support the notion
41 of an early morpho-orthographic decomposition process that is blind to semantics (and hence
42 unaffected by semantic transparency). In summary, a large body of evidence has been amassed to

6
7

8 **Masked priming with nonword primes**

9
10 A common variation of the masked morphological priming paradigm uses nonwords as
11 primes (e.g., Beyersmann, Casalis, Ziegler, & Grainger, 2015, Beyersmann, Cavalli, Casalis, and
12 Colé, 2016); Heathcote et al., 2017; Longtin & Meunier, 2005; McCormick, Brysbaert, & Rastle,
13 2009; McCormick, Rastle, & Davis, 2009; Morris, Porter, Grainger, & Holcomb, 2011). From a
14 methodological standpoint, the use of nonwords has some advantages. In particular, using
15 nonwords as primes makes it much easier to compare different prime conditions with the same
16 targets (morphological priming experiments with word primes usually require comparisons
17 across different word targets). Furthermore, it is potentially advantageous to use primes that are
18 not nonwords so as to minimise lexical influences (of words other than the target) on priming. It
19 is well-established that masked word form primes can give rise to inhibitory priming effects; for
20 example, a prime like *rocket* may result in slower lexical decision latencies to the target ROCK,
21 relative to an unrelated word prime (e.g., Davis & Lupker, 2006; De Moor & Brysbaert, 2000;
22 Segui & Grainger, 1990). This inhibitory priming effect may reflect competition between the
23 lexical representations of the prime and the target. By contrast, inhibitory priming effects are not
24 usually observed for nonword primes.
25

30
31
32
33
34
35
36
37
38
39
40
41
42
43
44
45

46 If letter strings containing (pseudo-)affixes automatically engage a morpho-orthographic
47 decomposition mechanism, it is reasonable to expect that nonword primes formed by combining
48 stems with affixes should give rise to similar priming effects as those observed with word primes
49 (e.g., *worder-WORD* should give similar priming effects to *corner-CORN* or *burner-BURN*).
50
51 Such results have indeed been observed. For example, McCormick et al. (2009) found that
52
53
54
55
56
57
58
59
60

1
2
3 priming for nonword primes like *alarmer-ALARM* was statistically equivalent to that obtained for
4
5 word primes like *national-NATION* and *notional-NOTION* (high and low frequency word primes,
6
7 respectively). They interpreted this result as “lending strong support to the notion of a routine
8
9 form of decomposition that is applied to all morphologically structured stimuli” (McCormick et
10
11 al., 2009, p. 1706).
12
13

14
15 However, caution is required when interpreting priming effects obtained with
16
17 morphologically complex nonword primes. A natural question to ask about such effects is
18
19 whether they might more parsimoniously be interpreted as reflecting purely orthographic, as
20
21 opposed to morpho-orthographic processing. After all, very similar priming effects are obtained
22
23 in orthographic form priming experiments in which there is no reason to suppose morphological
24
25 involvement. For example, Lupker, Zhang, Perry, and Davis (2015) examined the effect of
26
27 adding a consonant at the beginning or end of a word (e.g., *zjudge-JUDGE* or *judgez-JUDGE*)
28
29 and observed priming effects of greater than 30 ms. Note that such form priming effects do not
30
31 depend on preserving the contiguity of the target letters. For example, Grainger and colleagues
32
33 (Van Assche & Grainger, 2006; Welvaert, Farioli, & Grainger, 2008) have shown large priming
34
35 effects for primes in which non-target letters are inserted within the word (e.g., *musxtayrd-*
36
37 *MUSTARD*). The Form Priming Project (FPP; Adelman et al., 2014), a large-scale masked
38
39 priming experiment in which over 1000 participants were tested across 14 sites, found a 19 ms
40
41 priming effect for primes formed by inserting two random (non-repeat) letters within the target
42
43 word (e.g., *desaxign-DESIGN*). Related results on the perceptual similarity of orthographic
44
45 neighbours formed by letter addition/deletion have been observed in unprimed lexical decision
46
47 (Davis & Taft, 2005; Davis, Perea, & Acha, 2009), eye-tracking (Davis et al., 2009), and
48
49 semantic categorisation (Bowers, Davis, & Hanley, 2005). For example, Bowers et al. (2005)
50
51
52
53
54
55
56
57
58
59
60

1
2
3 found that participants took longer (and were less accurate) to reject the word *apex* (which has
4 the deletion neighbour *ape*) as a type of animal than to reject *apex* as a type of vehicle (and
5 conversely *scar* took longer to reject as a type of vehicle than as a type of animal). The
6
7
8
9
10 implication is that deletion neighbours are processed to the level of meaning, such that
11
12 performance is impaired when these neighbours would require a different response than the word
13
14 that was presented. It is important to emphasise that these empirical findings provided
15
16 confirmations of the predictions made by a computational model of orthographic processing
17
18 (Davis, 1999, 2010); the orthographic similarity of addition/deletion neighbours is also predicted
19
20 by other models of orthographic processing (e.g., Adelman, 2011; Grainger, Van Heuven, &
21
22 Bonin, 2003; Norris, Kinoshita, & Casteren, 2010; Whitney, 2001). In summary, finding that
23
24 *alarmer-ALARM* results in priming relative to an unrelated prime cannot be interpreted as
25
26 evidence for a morphological process, because such priming effects are predicted by models that
27
28 include no morphological processing.
29
30
31
32
33

34 One approach to attempt to establish that priming effects with complex nonword primes
35
36 do entail morphological processing would be to show that stronger priming is obtained for
37
38 (pseudo-)affixed nonword primes like *alarmer* than for non-affixed nonword primes like *alarmel*,
39
40 where form overlap is matched. Some experiments have reported such a difference (e.g., Longtin
41
42 & Meunier, 2005; McCormick et al., 2009). However, in these experiments the relevant
43
44 comparisons involved different targets and/or participants, which is not ideal. Furthermore, the
45
46 priming effects for non-affixed nonword primes did not attain significance in these experiments,
47
48 which is inconsistent with the usual pattern for orthographic form primes (e.g., Adelman et al.,
49
50 2014). By contrast, more recent investigations using within-item designs have tended to find
51
52 equivalent priming for non-interpretable affixed and non-affixed nonword primes (e.g.,
53
54
55
56
57
58
59
60

1
2
3 Beyersmann et al., 2015, 2016; Morris et al., 2011). Faced with these null effects, the most
4
5 straightforward conclusion would appear to be that the priming effects obtained with
6
7 morphologically complex nonword primes are driven entirely by form overlap, with no need to
8
9 posit any role for morphological decomposition or other morphological processing.
10
11

12 13 **Does semantic interpretability influence nonword priming?** 14

15
16 However, an alternative interpretation of these data, recently suggested by Heathcote et al.
17
18 (2017), is that the above-cited studies failed to find a difference in priming between affixed and
19
20 non-affixed nonwords because the affixed nonwords were semantically noninterpretable. In
21
22 support of this interpretation, Heathcote et al. (2017) reported a lexical decision experiment in
23
24 which affixed nonword primes that had been rated as semantically plausible resulted in
25
26 significantly greater priming than non-affixed control primes; for example, *cheapize-CHEAP*
27
28 resulted in greater priming than *cheapstry-CHEAP*. As they note, “The obvious advantage of
29
30 interpretable relative to non-interpretable complex novel words is that interpretable stem-affix
31
32 combinations generate meaning, whereas non-interpretable stem-affix combinations do not”.
33
34
35

36
37 Evidently readers are able to determine whether a novel affixed form is interpretable.
38
39 Faced with a novel word like *cheapize*, skilled readers are able to determine a likely
40
41 morphological structure and then use this to come up with a possible interpretation (e.g., “to
42
43 make cheap”). In particular, Heathcote et al. (2017) appealed to the notion of a licensing
44
45 mechanism governing the (re-)combination of stems and affixes (Schreuder & Baayen, 1995).
46
47 This mechanism succeeds for interpretable primes like *cheapize* but is unsuccessful for
48
49 uninterpretable and non-affixed primes, resulting in reduced priming effects. Potentially, then, the
50
51 mixed empirical findings may reflect differences in the proportion of interpretable primes (or
52
53 degree of prime interpretability) in different experiments.
54
55
56
57
58
59
60

1
2
3 As Heathcote et al. (2017) note, there are previous observations that provide support for
4 the role of interpretability. Most relevantly, Meunier and Longtin (2007) found that
5 morphologically complex pseudowords were effective primes of their stems in cross-modal
6 priming, but only if the pseudoword was interpretable. That is, priming was found for *rapidifier-*
7 *RAPIDE* (an English equivalent is *quickify-QUICK*), but not for *sportation-SPORT*. They
8 concluded that “semantic interpretability plays a major role during pseudoword recognition”
9 (p. 467). Other evidence for the role of interpretability (and support for a licensing mechanism)
10 comes from studies that have found that interpretable morphologically complex nonwords take
11 longer to reject in a lexical decision task than uninterpretable controls (Burani, Dovetto,
12 Spuntarelli, & Thornton, 1999; Coolen, Van Jaarsveld, & Schreuder, 1991; Wurm, 2000).
13
14
15
16
17
18
19
20
21
22
23
24
25
26

27 Nevertheless, the latter studies were not masked priming experiments, and do not
28 challenge the claim that early processing involves a semantically-blind orthographic parser.
29 Indeed, as outlined earlier, masked priming experiments showing the absence of semantic
30 transparency effects with word primes have led to an explanatory framework in which semantic
31 processing does not begin until later (Heyer & Kornishova, 2018; Rastle & Davis, 2008)¹. This
32
33
34
35
36
37
38
39
40
41
42

43 ¹ Semantic interpretability and semantic transparency are overlapping, though not perfectly
44 equivalent concepts. In the same way that nonwords cannot be said to be “regular” or “irregular”
45 (because they do not have a correct pronunciation), nonwords cannot be said to be semantically
46 “transparent” or “opaque”, given that their meaning is not defined. Nevertheless, it is legitimate
47 to speak of the semantic interpretability of a nonword, i.e., how readily readers are able to
48 determine a possible meaning of that nonword, based on its constituent morphemes. A related
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 time-course is consistent with semantic priming experiments: semantic/associative priming
4
5 effects only start to become robust for primes that are presented for around 80 ms (for a meta-
6
7 analysis, see Brysbaert, McCormick, Van der Haegen, Keuleers, & Davis, 2015). A relatively
8
9 deep level of semantic processing is required to determine that *cheapize* is interpretable, perhaps
10
11 more than one might expect could be afforded a masked prime. Thus, while interpretability is
12
13 undoubtedly a factor that influences processing of nonwords, stronger evidence is required to
14
15 support the claim that this factor exerts its influence sufficiently rapidly to provide an explanation
16
17 of differences in masked form priming effects for different nonword primes.
18
19
20
21

22
23 Furthermore, the claim that interpretability influences priming effects for masked nonword
24
25 primes is inconsistent with a previous examination of this issue. Longtin and Meunier (2005)
26
27 found equivalent priming from interpretable (*rapidifier-RAPIDE*) and non-interpretable
28
29 (*sportation-SPORT*) nonword primes. However, as noted earlier, these authors found no priming
30
31 for nonword primes with non-affixed endings (*rapiduit-RAPIDE*). Evidently the available
32
33 literature provides a somewhat mixed picture. Longtin and Meunier (2005)'s result raises the
34
35 possibility that the difference between interpretable and non-affixed primes observed by
36
37 Heathcote et al. (2017) could reflect the presence of an affix, rather than the interpretability of the
38
39 stem-affix combination. Indeed, Heathcote et al. (2017)'s experiment appears to be lacking the
40
41 full set of conditions required to support any conclusion regarding prime interpretability.
42
43
44
45
46
47
48
49
50

51
52 term is semantic plausibility, which is sometimes used by Heathcote et al. (2017); here we treat
53
54 “semantic plausibility” as synonymous with “semantic interpretability”.
55
56
57
58
59
60

1
2
3 In view of these considerations, a replication of Heathcote et al. (2017) was warranted. We
4
5 took a few steps to achieve a higher level of power than their original experiment: a) we greatly
6
7 increased the size of the stimulus set, b) we tested a relatively large number of participants, and c)
8
9 given that Heathcote et al. (2017) found that (numerically at least) the difference between the
10
11 interpretable affixed and (non-interpretable) non-affixed conditions was greater for suffixes than
12
13 for prefixes we decided to focus our power by restricting our attention to suffixes. Critically, we
14
15 added a new prime condition comprising uninterpretable affixed nonwords, i.e., nonwords
16
17 formed by stem-affix combinations that are not readily interpretable (e.g., *maskity*). If the
18
19 difference reported by Heathcote et al. (2017) is a genuine interpretability effect there should be
20
21 greater priming for prime-target pairs like *maskless-MASK* than for pairs like *maskity-MASK*. . If
22
23 our findings do support Heathcote et al (2017), then our study would be inconsistent with the
24
25 trend in the literature reporting lack of semantic transparency effects during early processing.
26
27
28
29
30
31

32 Method

33 Participants

34
35
36 There were 122 participants in total. Of these, 73 participants were tested at the University
37
38 of Bristol and 49 at the University of Hull. At both sites the participants were psychology
39
40 undergraduates who participated in exchange for course credit; all had normal or corrected-to-
41
42 normal vision. The study was approved by the University of Bristol Faculty of Science Research
43
44 Ethics Committee and the University of Hull Faculty of Health Sciences Ethics Committee, and
45
46 all participants provided their informed consent.

Stimuli and Design

The experiment used a within-subjects design in which the independent variable was Prime Type and the dependent variables were reaction time and accuracy. The four prime types were: a) interpretable affixed nonwords, b) uninterpretable affixed nonwords, c) nonaffixed nonwords, and d) unrelated primes. A Latin square design was used to rotate the prime stimuli across targets, resulting in four counterbalanced lists. There were 208 target stimuli, half of which were real words. Three-eighths of the target stimuli were drawn from Heathcote et al. (2017)'s items, to which we added a further 130 stimuli. The target words were all monomorphemic, ranging in frequency from 0.6 to 510 per million (mean = 87.7, SD = 112.4), and in length from 3 to 7 letters (mean = 4.8, SD = 0.9). Each of the target words was a stem morpheme in at least one polymorphemic English word (for example, *round* is the stem of the word *roundness*). Related primes were formed by adding an affix or a non-affix letter string to these stems. Following Heathcote et al. (2017), no orthographic alterations were made to stems when adding suffixes (e.g., final *e* was not dropped when adding an initial-vowel suffix).

Interpretable primes were created by combining each stem with a suffix to form a semantically plausible nonword (e.g., the suffix *-less* was added to the stem *mask* to generate the nonword *maskless*). In the case of target stimuli drawn from Heathcote et al. (2017), we used the same primes as in their experiment. For the new targets we obtained subjective evaluations of the plausibility of multiple candidate suffixed forms from a small group of native speakers (mostly undergraduates), who rated plausibility on a scale from 1 (not plausible) to 5 (very plausible). Interpretable affixed nonwords were judged as plausible (at least 3 out of 5) by at least half of the raters. Uninterpretable nonwords (e.g., *maskity*) were created in the same way as interpretable

1
2
3 primes, except that the resulting affixed nonword was rated as implausible by at least half of the
4
5 raters.
6
7

8
9 Non-affixed nonword primes were created by combining stems with a string of letters
10
11 which were not suffixes (e.g., *ort*, *lem*). We attempted to minimise orthographic overlap between
12
13 the stem and letter string endings, although some overlap could not be avoided. The unrelated
14
15 prime condition comprised affixed words that shared no more than two letters with their
16
17 corresponding targets (e.g., *prideful-ACID*). Stimulus characteristics for the primes paired with
18
19 word targets are shown in Table 1.
20
21

22
23 --- Insert Table 1 about here ---
24
25

26
27 Pronounceable nonword stimuli were created by changing one or two letters of
28
29 corresponding word targets. Primes were constructed by applying the same changes to the
30
31 corresponding related primes. For example, the nonword target *MISK* was constructed by
32
33 changing the *a* in *MASK* to an *i*, and the related primes then became *miskless*, *miskity* and
34
35 *miskond*. The same unrelated primes were used for the corresponding word targets (e.g., the word
36
37 target *MASK* and the nonword target *MISK* were both preceded by the unrelated prime *tubeful*).
38
39 Items were counterbalanced so that a participant would not see a word and a nonword target it
40
41 was derived from (i.e., they wouldn't see *MASK* and *MISK*). The full set of stimuli for this
42
43 experiment, as well as the raw data, can be found at <https://osf.io/7y2ve/>.
44
45
46
47

48 **Procedure**

49

50
51 Participants were seated approximately 60 cm in front of a monitor attached to a PC
52
53 running Microsoft Windows 7. DMDX software (K. I. Forster & Forster, 2003) was used to
54
55 present the stimuli and record the reaction time and accuracy of responses. Each trial began with
56
57
58
59
60

1
2
3 a forward mask (#####) that was displayed for 500 ms in the centre of the screen. The
4
5 prime was then presented in lower case for approximately 50 ms, followed by the target which
6
7 was presented in upper case until the participant responded (or until the trial timed out after 2
8
9 seconds). All stimuli were presented in white Courier New font on a black background. Primes
10
11 were presented in 12 point font; the size of the target and mask stimuli was 50% greater (i.e., 18
12
13 point). Participants were instructed to decide whether each stimulus was a word or nonword as
14
15 fast as possible without making too many errors. They used the left and right control keys to
16
17 make nonword and word responses respectively. Feedback (the word “Wrong”) was given on
18
19 trials to which participants made incorrect responses or failed to respond within 2500 ms. The
20
21 experiment proper was preceded by eight practice trials. This part of the experiment took between
22
23
24
25
26 10 and 15 minutes.

27
28
29 Immediately following the lexical decision task, participants made ratings of the semantic
30
31 plausibility of 52 nonwords, which were presented one at a time on the screen. These nonwords
32
33 corresponded to the affixed primes that had been presented to that participant, preceding word
34
35 targets, although there was no mention of any relationship between the two parts of the
36
37 experiment. As in the pre-test, participants indicated the plausibility of each nonword on a scale
38
39 of 1 to 5 (1 being not plausible and 5 being very plausible). This part of the experiment took
40
41
42 around five minutes.

43 44 45 46 **Data analysis**

47
48
49 We used R (Version 3.5.1; R Core Team, 2018) and the R-packages *BayesFactor* (Version
50
51 0.9.12.4.2; Morey & Rouder, 2018), *bindrepp* (Version 0.2.2; Müller, 2018), *coda* (Version

59
60

1
2
3 2009), *Matrix* (Version 1.2.14; Bates & Maechler, 2018), *papaja* (Version 0.1.0.9842; Aust &
4
5 Barth, 2018), and *rstudioapi* (Version 0.7; Allaire, Wickham, Ushey, & Ritchie, 2017) for our
6
7 analyses.
8
9

11 Results

15 Interpretability ratings

18
19 --- Insert Figure 1 about here ---
20
21

22 Each of the affixed nonwords was rated by at least 30 participants. A response key other
23 than digits 1 through 5 was recorded for 0.8% of the ratings, and these responses were discarded;
24 for the remaining responses the median rating was 3 and the modal rating was 1. The most
25 interpretable nonword was “maskless” (given a rating of 5 by 83% of raters) and the least
26 interpretable nonword was “happyation” (given a rating of 1 by 71% of raters, and a rating of 2
27 by a further 26%). An interpretability score was computed for each nonword based on its mean
28 rating; these scores can be found at <https://osf.io/7y2ve/>.
29
30
31
32
33
34
35
36
37
38

39 In general, the preliminary assignment of nonwords to interpretability conditions was
40 supported, such that the interpretable condition was associated with significantly higher scores
41 than the uninterpretable condition, Welch’s $t(177.37) = 17.43, p < .001$. However, there was
42 some overlap between the conditions, which was mostly due to nonwords that we had originally
43 assigned as interpretable, but which were rated as relatively uninterpretable by participants (this
44 included several items of our construction, e.g., “scarfness”, “musicize”, but also several of
45 Heathcote et al. (2017)’s items, e.g., “bulber”, “cheapize”). In addition, there were five nonwords
46 that we had assigned to the uninterpretable condition that participants rated as relatively
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 interpretable (e.g., “stuntness”, “breakism”). To ensure a clear separation of the two
4
5 interpretability conditions, we used the median interpretability score plus or minus 0.05 to form
6
7 cutoffs, excluding from further analysis any “interpretable” nonwords with scores of less than
8
9 2.65, and any “uninterpretable” nonwords with scores of more than 2.55. Also, nonwords whose
10
11 ratings did not support their initial classification were re-assigned to the other condition if the
12
13 ratings met the other condition’s criterion for inclusion. For example, if a nonword originally
14
15 assigned as “interpretable” was rated as “uninterpretable”, then the nonword would be re-
16
17 classified as “uninterpretable”. The exclusion of target words in which one or both of the
18
19 associated affixed nonwords did not satisfy this criterion resulted in the elimination of 28 items,
20
21 leaving us with 76 target words. Of the excluded items, 11 were from Heathcote et al. (2017)’s
22
23 stimuli. Figure 1 presents histograms of interpretability scores for the two nonword conditions
24
25 following item exclusions.
26
27
28
29
30

31 **Lexical decision data**

32 **Data Cleaning**

33
34
35
36
37 Targets for which one or both nonword primes failed to satisfy the above rating criteria
38
39 were treated as fillers, and were not included in the analysis of lexical decision data. Initial
40
41 inspection of these data revealed one word target that was associated with a high error rate
42
43 (greater than 2.5 SDs more than the mean). This target (FRILL) was excluded from further
44
45 analysis. The same criterion led to the exclusion of four nonwords. The resulting set of target
46
47 stimuli comprised 75 words and 98 nonwords.
48
49
50

51
52 Median accuracy across participants was 93.64%, and all but one participant had mean
53
54 accuracies of greater than 75% correct; this error-prone participant was excluded from further
55
56
57
58
59
60

1
2
3 analysis, as was one participant whose mean RT was more than 3 SDs slower than the mean.
4
5 Following these exclusions there were 30 participants for each of the four counterbalanced
6
7 versions of the experiment.
8
9

10
11 Erroneous responses were excluded from the analysis of reaction times, as were responses
12
13 faster than 150 ms or slower than 1500 ms (1.18% of trials).
14
15

16 **Words**

17
18
19
20 --- *Insert Table 2 about here* ---
21
22

23 Table 2 shows mean reaction time and error rates for each prime condition. Along with
24
25 analysis using null hypothesis significance testing, we also provide Bayes Factors (calculated
26
27 using the BayesFactor R package; Rouder, Morey, Speckman, & Province, 2012) for the three
28
29 key comparisons of interest (the evidence of priming for the three prime types), which provides a
30
31 quantitative measure of evidence for or against the null hypothesis. The main effect of prime
32
33 condition on RT was statistically significant, $F_1(3, 357) = 5.09, p = .002$; $F_2(3, 222) = 4.80, p =$
34
35 $.003$. Specifically, the three related conditions showed significant priming relative to the
36
37 unrelated condition by subjects, $t_1(119) = 4.11, p < .001, BF_{10} = 227.98$, and by items,
38
39 $t_2(74) = 3.46, p = .001, BF_{10} = 26.9$. However, the mean RT for the affixed conditions did not
40
41 differ from the non-affixed condition, $t_1(119) = 0.99, p = .323, BF_{10} = 0.16$; $t_2(74) = 1.05, p =$
42
43 $.295, BF_{10} = 0.22$. Critically, there was no difference between the interpretable and
44
45 uninterpretable affixed conditions, $t_1(119) = 0.25, p = .802, BF_{10} = 0.1$; $t_2(74) = 0.36, p = .718,$
46
47 $BF_{10} = 0.14$. These non-significant results with Bayes Factors all lower than $\frac{1}{3}$ provide moderate
48
49 to strong evidence for the null hypothesis of no priming effect (Stefan, Gronau, Schönbrodt, &
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Wagenmakers, 2019). The analysis of accuracy data showed no effect of prime condition, $F(3,$
4 $357) = 0.48, p = .694$; $F(3, 222) = 0.49, p = .689$.

5
6
7
8
9 --- Insert Figure 2 about here ---

10
11
12 To check that a possible role of interpretability had not been masked by discretisation of
13 this variable, we examined its continuous effect for the full set of 208 affixed nonword primes.
14 Priming effects (relative to the unrelated condition) were computed for each of the affixed
15 primes. As can be seen in Figure 2, the item-level data showed no indication of any positive
16 relationship between nonword interpretability ratings and priming effects; there was a small, non-
17 significant, negative correlation ($r = -0.06, n = 208, p = .377$).

26 **Nonwords**

27
28
29
30 --- Insert Table 3 about here ---

31
32
33 Table 3 shows mean reaction time and error rates for nonwords in each prime condition.
34 As can be seen, each of the condition means was within 3 ms of the grand mean, i.e., there was
35 no difference in mean RT across conditions, $F(3, 357) = 0.44, p = .727$; $F(3, 291) = 0.36, p =$
36 $.779$. Similarly, the analysis of accuracy data showed no effect of prime condition, $F(3, 357) =$
37 $0.25, p = .860$; $F(3, 291) = 0.20, p = .897$.

46 **Discussion**

47
48
49
50 The main goal of this experiment was to determine whether semantic interpretability
51 influences masked priming for nonword primes, as suggested in a recent article by Heathcote et
52 al. (2017). The results were unambiguous in showing that semantic interpretability had no
53
54
55
56
57
58
59
60

1
2
3 influence on priming: equivalent priming was obtained for the interpretable and uninterpretable
4 prime conditions.
5
6

7
8 The reader will note that we are in the (not uncommon) position of claiming a null effect
9 of a variable for which an effect has previously claimed. We would address this concern in four
10 ways. First, we believe that it is unlikely that our null effect reflects a lack of statistical power.
11 Our analysis of reaction times for words includes over 2100 observations per prime condition (by
12 contrast, Heathcote et al. (2017)'s experiment had 30 participants and 18 targets per prime
13 condition, giving approximately 500 observations per condition). Secondly, the difference in
14 mean RT between the interpretable and uninterpretable affixed prime conditions was 0.5 ms.
15 Thirdly, Bayes Factors for the critical contrast (0.1 by-participants and 0.14 by-items) showed
16 moderate to strong evidence in support of the null hypothesis, where less than 0.3 is considered
17 moderate and less than 0.1 as strong evidence (Stefan et al., 2019). While this level of evidence
18 might not be considered definitive, due to the slow rate of evidence accumulation for a true null
19 as sample size increases (and particularly for default priors; Stefan, Gronau, Schönbrodt, &
20 Wagenmakers, 2019) much larger sample sizes are necessary for stronger evidence (Brysbaert,
21 2019). This has led to < 0.33 being suggested as a reasonable threshold to achieve to support the
22 null hypothesis (Brysbaert, 2019). Finally, Figure 2 and the lack of significant correlation
23 between interpretability and item-level priming suggests that the failure to find an effect of
24 interpretability was not due to the dichotomisation of this variable in the ANOVA.
25

37
38
39
40
41
42
43
44
45
46
47

48 However, perhaps the most important point to make in this respect is that our null effect
49 does not represent a failure to replicate a significant effect, but rather the inclusion of a critical
50 condition that was not present in Heathcote et al. (2017)'s experiment. The absence of an
51 uninterpretable affixed nonword prime condition from their experiment means that the claim of
52
53
54
55
56
57
58
59
60

1
2
3 an effect of interpretability rests on a comparison between interpretable affixed nonword primes
4 and non-affixed nonword primes. The difficulty here is that such a comparison may reflect
5 factors other than interpretability, most obviously the difference between affixes and non-affixes
6 (though other uncontrolled factors may also be at work). To be fair to Heathcote et al. (2017),
7 their conclusion was influenced by a body of prior empirical data that has presented a somewhat
8 confusing picture as to whether there is a difference between affixed and non-affixed nonword
9 primes, and the results of their experiment were presented as a possible reconciliation of this
10 confusion.
11
12
13
14
15
16
17
18
19
20
21

22 It could be argued that our findings differ from Heathcote et al's (2017) because we only
23 used suffixed primes. Previous studies have demonstrated differences between how prefixed and
24 suffixed primes are processed (e.g. Beyersmann, Ziegler, & Grainger, 2015; Kim, Wang, & Taft,
25 2015). Therefore, one may suggest that inclusion of prefixed primes would have increased our
26 chances of reporting a semantic transparency effect. However, this still does not provide a
27 sufficient reason of why our results are inconsistent with Heathcote et al (2017) since they found
28 no significant difference in priming between suffixed and prefixed primes.
29
30
31
32
33
34
35
36
37
38

39 Indeed, rather than being a failure to replicate, our results are consistent with those of
40 Longtin and Meunier (2005), who found equivalent priming from interpretable (*rapidifier-*
41 *RAPIDE*) and non-interpretable (*sportation-SPORT*) nonword primes. Furthermore, finding no
42 effect of semantic interpretability for nonword primes aligns with the general finding of no
43 semantic transparency effects for masked word primes (Rastle & Davis, 2008).
44
45
46
47
48
49
50

51 Another difference between our findings and those of Heathcote et al. (2017) is that we
52 found no difference between affixed and non-affixed nonword primes. Given the equivalence of
53
54
55
56
57
58
59
60

1
2
3 the interpretable and uninterpretable affixed conditions, we can eliminate the possible confound
4
5 of interpretability (i.e., we found no difference between uninterpretable affixed pairs like *maskity-*
6
7 *MASK* and uninterpretable non-affixed pairs like *maskond-MASK*). It is not clear why our result
8
9 differs from Heathcote et al. (2017)'s, but it is consistent with the findings reported in other
10
11 recent experiments that found equivalent priming for affixed and non-affixed nonword primes
12
13 (e.g., Beyersmann et al., 2015, 2016; Morris et al., 2011). Then again, as noted earlier, the initial
14
15 investigations of this issue did find significant differences favouring affixed primes (Longtin &
16
17 Meunier, 2005; McCormick et al., 2009), and we observed a numerical difference of 5 ms in this
18
19 direction. The present data do not allow us to rule out the possibility that there is a small effect of
20
21 nonword affixation to be found. Nevertheless, we would reiterate that our experiment was
22
23 relatively high-powered by comparison with other experiments in this field, which mostly
24
25 comprise experiments with fewer than 1000 data points per condition, and often fewer than 500
26
27 (see Davis & Rastle, 2010 for relevant funnel plots for experiments with word primes). Brysbaert
28
29 and Stevens (2018) recommend that at least 1600 observations are required in repeated measures
30
31 priming experiments that aim to detect effect sizes of around 15 ms. The danger associated with
32
33 small sample sizes is not only that real effects may not be detected but also that the imprecision
34
35 of measurement may lead to Type I errors, i.e., the “detection” of effects that are not really
36
37 present (e.g., Button et al., 2013). A resolution of this empirical uncertainty is forthcoming, as the
38
39 most recent form priming project (FPP2), which includes approximately 17,000 data points per
40
41 condition, has compared pseudo-prefixed, pseudo-suffixed and orthographic control conditions.²
42
43
44
45
46
47
48
49

50
51
52 ² Preliminary results presented by Davis (2018) show no difference between the pseudo-affixed
53
54 and orthographic control conditions.
55
56
57
58
59
60

1
2
3 We emphasise that our claim is not that semantic transparency is not an important factor,
4 but rather that it does not emerge sufficiently rapidly to influence masked priming. This account
5 agrees with the explanatory framework proposed by Rastle and colleagues based on experiments
6 with word primes (Rastle & Davis, 2008; Rastle et al., 2000). As noted earlier, Heyer and
7 Kornishova (2018) have recently presented converging evidence on this point, finding no
8 evidence of semantic transparency when the prime duration was 33 ms or 39 ms, but a significant
9 effect of transparency when the prime was presented for 67 ms or 77 ms; they also review the
10 extant literature, and note that (with one exception, where methodological differences may have
11 contributed) “significantly stronger priming for transparent in comparison to opaque items
12 emerged only at SOAs of 50 ms or more” (p. 1121). That is, semantic transparency effects appear
13 when the prime is presented for a duration sufficient to make conscious report possible. That is,
14 semantic transparency effects appear to be restricted to situations in which the prime is presented
15 so briefly that it is not unavailable for conscious report; when primes are perceptible, clear effects
16 of transparency emerge. Whether or not conscious awareness of primes is critical is not clear. It
17 may rather be that primes of 60 ms duration or more offer sufficient time for a deeper level of
18 semantic processing, or enough time to allow a longer-lasting record of the prime to be
19 established, which can be processed semantically after the offset of the prime. It may take longer
20 for semantic information to become available for novel (interpretable) pseudoword primes than
21 for familiar word primes. Direct comparison of the time-course of semantic transparency and
22 semantic interpretability effects may be an interesting avenue for future experiments.

45
46
47
48
49

50 Ultimately, the question still remains on how corner facilitates (rather than inhibiting) the
51 target CORN and also, why recent masked nonword priming literature, including our study,
52 report no difference in priming between affixed and non-affixed nonword primes. A recent
53
54
55
56
57
58
59
60

1
2
3 proposal by Grainger and Beyersmann (2017) may potentially address both of these questions.
4
5 They propose that morphological processing is triggered by stem activation. Stem activation is
6
7 achieved by an edge-aligned stem activation mechanism which takes advantage of the fact stems
8
9 are either part of the first or last letter of a morphologically complex word. Grainger and
10
11 Beyersmann (2017) answers the question of why a pseudo-affixed prime such as corner facilitates
12
13 the target CORN and yet a non-affixed prime like cashew inhibits the target CASH. They argue
14
15 *the prime cashew acts a lexical competitor against the target CASH and thus stem activation is*
16
17 *inhibited.* In contrast, the presence of the pseudo-affix in corner triggers morpho-orthographic
18
19 decomposition and in turn, enables stem activation. The edge-aligned stem activation mechanism
20
21 also addresses why nonword priming studies find no difference in priming between affixed and
22
23 non-affixed primes. By definition, nonword primes are not contained in the lexicon. Therefore,
24
25 stem activation is able to be activated regardless of whether the nonword primes are affixed or
26
27 non-affixed. This is since neither types of nonwords act as lexical competitors against the target.
28
29
30
31
32
33

34 Recent research appears to support the proposal of an edge-aligned stem activation
35
36 mechanism. For example, Beyersmann and Grainger (2018) used the masked priming paradigm
37
38 to investigate whether priming effects are modulated by morphological family size.
39
40 Morphological family size is the number of different morphologically complex contexts in which
41
42 a word can appear in. The results suggests morphological family size does indeed influence the
43
44 size of priming effects where primes with a larger family size results in greater priming. This
45
46 indicates lexical or supra-lexical representations are involved in activating words embedded in a
47
48 morphologically complex word which is consistent with Grainger and Beyersmann's (2017)
49
50 proposal. Another study which supports Grainger and Beyersmann's (2017) proposal is
51
52 Beyersmann et al. (2018). They compared priming effects between stems which were either edge-
53
54
55
56
57
58
59
60

1
2
3 embedded (e.g. pimebook-BOOK) mid-embedded (e.g. pibookme-BOOK) or outer-embedded
4
5 (e.g. bopimeok-BOOK) in primes. Priming effects were only found for edge-aligned stems. This
6
7 indicates activation of embedded words are influenced by edge-alignedness which, again, is in
8
9 line with Grainger and Beyersmann's (2017) proposal. Considering Beyersmann and Grainger's
10
11 (2018) and Beyersmann et al's (2018) results, the proposal for an edge-aligned stem activation
12
13 mechanism, so far, appears to be promising in explaining how morphological processing is
14
15 implemented.
16
17
18
19

20 Overall, the picture that emerges from our experiment with affixed nonword primes is
21
22 consistent with the larger literature on orthographic form priming. Existing computational models
23
24 of masked form priming are able to capture these results, despite including no morphological
25
26 representations (e.g., Adelman, 2011; Davis, 2010, 2018). It may be that results that have been
27
28 characterised as demonstrating morpho-orthographic decomposition are more parsimoniously
29
30 characterised as further demonstrations of position-invariant orthographic input coding. This does
31
32 not undermine the fact that there is something morphological to be explained – in particular,
33
34 existing orthographic processing models do not explain the pattern observed with pseudo-derived
35
36 word primes like *corner*. From the perspective of models such as the spatial coding model
37
38 (Davis, 2010), the question to be answered is why *corner* facilitates (rather than inhibiting) the
39
40 target *CORN*. Our results help to constrain the set of possible answers by arguing against the
41
42 possibility that affixes are automatically and inevitably stripped from masked primes.

Figure 2: Item-Level Priming Effects As A Function Of Mean Subjective Interpretability For All Affixed Nonwords.

Table 1

Characteristics of prime stimuli.

Condition	Example	Length		Affix		SLBF		N	
		Length	SD	Length	SD	SLBF	SD	N	SD
Interpretable	maskless	8.42	1.01	3.58	0.69	16.67	3.34	0.14	0.38
	- MASK								
Uninterpretable	maskity	8.42	1.20	3.58	0.92	17.92	4.40	0.10	0.41
	- MASK								
Non-affixed	maskond	8.44	1.02	3.60	0.51	14.97	2.90	0.01	0.10
	- MASK								
Unrelated	tubeful -	8.38	1.04	3.54	0.67	16.76	3.24	0.19	0.59
	MASK								

Note. SLBF = Sum Log Bigram Frequency

Table 2

Mean correct reaction times, standard deviations and standard errors and priming effects in ms, and error rates for target words in each prime condition.

Condition	RT (ms)	n	SD	se	Priming	ER
Interpretable	610	2128	158	3.43	17	0.05
Uninterpretable	611	2114	152	3.31	16	0.05
Non-affixed	615	2119	156	3.39	11	0.05
Unrelated	627	2124	154	3.35		0.05

Note. Priming is calculated with respect to unrelated baseline

Table 3

Mean correct reaction times, standard deviations and standard errors and priming effects in ms, and error rates for target nonwords in each prime condition.

Condition	RT (ms)	n	SD	se	Priming	ER
Interpretable	712	2626	186	3.63	0	0.09
Uninterpretable	711	2642	185	3.60	1	0.09
Non-affixed	708	2630	186	3.62	4	0.09
Unrelated	712	2644	182	3.55		0.09

Note. Priming is calculated with respect to unrelated baseline
